Because of the mechanisms involved in cardiac rupture, associated multisystem injuries are common. More than 70% of reported survivors of myocardial rupture have other major associated injuries, including pulmonary contusions, liver and spleen lacerations, closed head injuries, and major fractures.

The immediate ability of the patient to survive cardiac rupture depends on the integrity of the pericardium. Two-thirds of patients with cardiac rupture have an intact pericardium and are protected from immediate exsanguination. These patients may survive for a brief period but will then develop significant hemo-pericardium and pericardial tamponade. One-third of patients with cardiac rupture have associated pericardial tears and succumb promptly to exsanguination.

Clinical Features

The clinical presentation of a patient who has sustained a myocardial rupture is usually that of cardiac tamponade or severe hemorrhage. Rarely, a patient is seen with a large hemothorax, hypotension, and hypovolemia, obscuring the diagnosis by mimicking a serious pulmonary or other intrathoracic injury. A patient with an intact pericardial sac and developing tamponade displays physical findings of tamponade, usually with subsequent clinical deterioration. Initial inspection of the torso may reveal little more than a bruised area over the sternum or no external physical evidence. More often, however, signs of significant chest trauma or other associated injuries will be present, indicating a mechanism of injury that could result in myocardial rupture. Auscultation may reveal a harsh murmur, known as a bruit de moulin,
Diagnostic Testing

Early use of ED ultrasound may facilitate the early diagnosis of cardiac rupture and pericardial tamponade. The combination of shock and JVD in a patient with blunt chest trauma should immediately suggest pericardial tamponade or tension pneumothorax, both conditions rapidly assessable by bedside ultrasound. In patients with coexistent hemorrhage from other injuries, JVD may be absent. Other considerations include myocardial contusion, superior vena cava obstruction, and ruptured tricuspid valve. Sonographic visualization of pericardial fluid in this setting should be followed by emergent thoracotomy (Fig. 38.17).

A chest radiograph may be helpful in patients suspected of having sustained trauma severe enough to cause myocardial rupture. Although this study usually does not help diagnose cases of myocardial rupture, it notes the presence of other intrathoracic injuries (eg, hemothorax, pneumothorax, and signs of possible aortic dissection). An increase in the size of the cardiac silhouette more commonly reflects preexisting disease or valvular incompetence with chamber enlargement caused by increased filling pressures. ECG changes may occur with myocardial injury, but these are often nonspecific. Bedside echocardiography in the ED should be performed in any case of suspected cardiac rupture, pericardial tamponade, a previously undiagnosed murmur, or shock unexplained by other causes (eg, exsanguination).

Management

When nonhospital medical personnel evaluate a patient who has sustained blunt chest trauma, they should concentrate on rapid transport and observe for any signs of pericardial tamponade. If examination is consistent with tension pneumothorax, this should be treated with needle decompression.

In the ED, treatment of patients with a myocardial rupture is directed toward immediate decompression of cardiac tamponade and control of hemorrhage. Pericardiocentesis may be effective in cases of a small rupture, but it is usually performed as a diagnostic or temporizing therapeutic procedure until surgical correction can be undertaken. Emergency thoracotomy and pericardiectomy may be required in the ED if the patient has rapidly deteriorating vital signs or a cardiac arrest. After emergency thoracotomy and pericardiectomy, the myocardial rupture should be controlled until the patient can be transported to the operating room for definitive repair. Hemorrhage from a ruptured atrium can often be controlled by finger occlusion or application of a vascular clamp. Insertion of a Foley catheter through the defect, followed by inflation of the balloon and traction on the catheter, may also control the bleeding. Ventricular rupture can usually be controlled by direct digital pressure or by suturing with nonabsorbable vascular sutures.

Cardiopulmonary bypass is required in only 10% of successful repairs of myocardial rupture. Therefore, for patients with suspected myocardial rupture, it is appropriate to undertake emergency thoracotomy in institutions that have qualified surgeons but no immediate access to cardiopulmonary bypass.

PENETRATING CARDIAC TRAUMA

Penetrating cardiac injuries are one of the leading causes of death in the setting of urban violence, with patients who survive to hospital arrival having a mortality rate of almost 80%. Improvements in emergency medical services, along with an emphasis on rapid transport, are responsible for an increasing number of cardiac injury patients arriving in impending or full cardiopulmonary arrest at busy urban trauma centers.\(^\text{35}\) The proportion of gunshot wounds versus stab wounds varies widely in reported case series, depending on the location of the trauma center.

The right ventricle is affected more often (43%) than the left ventricle (34%) owing to its anterior anatomic location. The left or right atrium is affected in 20% of cases. One-third of penetrating cardiac wounds affect multiple chambers, and survival is much worse in these cases.\(^\text{36}\) In 5% of cases, a coronary artery is lacerated, although these injuries usually involve a distal segment of the artery and rarely produce significant acute MI when they are ligated. More proximal coronary artery lacerations require coronary bypass. Rarely, the interventricular septum, a valve, papillary muscle, or chordae tendineae are lacerated, producing an acute shunt or valvular insufficiency. These lesions are poorly tolerated and can quickly produce massive pulmonary edema and cardiogenic shock.

Two conditions may occur after penetrating heart injury: (1) exsanguinating hemorrhage if the cardiac lesion communicates freely with the pleural cavity, or (2) cardiac tamponade if the hemorrhage is contained within the pericardium. Patients with exsanguinating wounds frequently die before they reach medical attention, or they have rapidly progressive hemorrhagic shock on presentation, culminating in cardiac arrest. This presentation is most typically seen in patients sustaining gunshot wounds to the heart. Cardiac tamponade is a life-threatening condition but appears to offer some degree of protection and increased survival in patients with penetrating cardiac wounds. These patients often require immediate resuscitation by emergency department thoracotomy (EDT) if they meet the criteria listed in Box 38.4.

**BOX 38.4**

**Indications for Emergency Department Thoracotomy**

**PENETRATING TRAUMATIC CARDIAC ARREST**

Cardiac arrest at any point with initial signs of life in the field
- Systolic blood pressure below 50 mm Hg after fluid resuscitation
- Severe shock with clinical signs of cardiac tamponade

**BLUNT TRAUMA**

Cardiac arrest in the emergency department (ED)
**ACUTE PERICARDIAL TAMPONade**

**Principles**

**Background and Importance**

The reported incidence of acute pericardial tamponade is approximately 2% in patients with penetrating trauma to the chest and upper abdomen; it is rarely seen after blunt chest trauma. It occurs more commonly with stab wounds than with gunshot wounds, and 60% to 80% of patients with stab wounds involving the heart develop tamponade. Patients with acute pericardial tamponade can deteriorate in minutes, but many can be saved if proper steps are taken.

**Pathophysiology**

The primary feature of a pericardial tamponade is an increase in intrapericardial pressure and volume. As the volume of the pericardial fluid encroaches on the capacity of the atria and ventricles to fill adequately, ventricular filling is mechanically limited, and thus the stroke volume is reduced. This results in decreased cardiac output and ultimately diminished arterial systolic blood pressure and decreased pulse pressure. As little as 60 to 100 mL of pericardial blood may produce the clinical picture of tamponade. Concomitantly, CVP rises because of the mechanical backup of blood into the vena cava.

Several compensatory mechanisms then occur. The heart rate and total peripheral resistance rise in an attempt to maintain adequate cardiac output and blood pressure. A less effective compensatory response, resulting in a greater rise in CVP, is an increase in veno-motor tone caused by contractions of the smooth muscles within the wall of the vena cava.

The diagnosis of pericardial tamponade should be suspected in any patient who has sustained a penetrating wound or blunt trauma to the thorax or upper abdomen. One is never certain of the trajectory of the bullet or the length, force, and direction of a knife thrust on initial evaluation. Obviously, wounds directly over the precordium and epigastrium are more likely to produce a cardiac injury resulting in tamponade than those in the posterior or lateral thorax. Nevertheless, it is assumed that a penetrating wound, particularly a gunshot wound, anywhere in the thorax or upper abdomen may have injured the heart. Rapid bedside echocardiography, performed as part of the standard FAST examination, easily detects a pericardial effusion causing cardiac tamponade.

**Clinical Features**

Patients with cardiac tamponade may initially appear deceptively stable if the rate of bleeding into the pericardial space is slow or if the pericardial wound allows intermittent decompression. Other patients may complain primarily of difficulty breathing, which suggests pulmonary rather than cardiac pathology.

The physical findings of pericardial tamponade—hypotension, distended neck veins, and, rarely, distant or muffled heart tones (known as Beck’s triad)—may be difficult to identify clinically, especially in the midst of a major resuscitation with concomitant hypovolemia, when the neck veins may be flat. Although the most reliable signs of pericardial tamponade are an elevated CVP (>15 cm H₂O) in association with hypotension and tachycardia, bedside echocardiography performed as part of the FAST examination rapidly diagnoses pericardial tamponade (by identifying pericardial fluid with concomitant tamponade physiology) and has largely replaced the use of CVP measurements to make the diagnosis. Echocardiography also distinguishes pericardial tamponade versus tension pneumothorax when the triad of elevated CVP, hypotension, and tachycardia is present.

Acute pericardial tamponade may be seen with three distinct clinical pictures. If the hemorrhage is confined to the pericardial space, the patient is initially normotensive but will have a tachycardia and elevated CVP. If untreated, most of these patients go on to develop hypotension. If significant hemorrhage has occurred outside the pericardial sac, either through a tear in the pericardium or from associated trauma, the clinical picture is that of hypovolemic shock with hypotension, tachycardia, and a low CVP. If the CVP rises to a level of 15 to 20 cm H₂O with volume replacement but hypotension and tachycardia persist, pericardial tamponade should be considered. The third clinical picture is that of an intermittently decompressing tamponade due to intermittent hemorrhage from the intrapericardial space, partially relieving the tamponade. The clinical picture may wax and wane depending on the intrapericardial pressure and volume and total blood loss. In general, this condition is compatible with a longer survival than are the first two clinical presentations.

Pulsus paradoxus is defined as an excessive drop in systolic blood pressure during the inspiratory phase of the normal respiratory cycle. This sign may be an additional clue to the presence of pericardial tamponade, but it is often difficult to measure during an intensive resuscitation or in the presence of shock.

**Diagnostic Testing**

**Radiology**

**Ultrasound.** Ultrasound enables rapid, accurate, and noninvasive diagnosis of pericardial tamponade. This study can be performed at the bedside in the ED during the initial resuscitation of the patient as part of the FAST examination. Although the sonographic definition of tamponade is the simultaneous presence of pericardial fluid and diastolic collapse of the right ventricle or atrium, the presence of pericardial fluid in a patient with chest trauma is highly suggestive of pericardial hemorrhage (see Fig. 38.17). An indirect sonographic sign of tamponade is the demonstration of a dilated inferior vena cava in a hypotensive patient. EDs in which cardiac ultrasonography is performed with subcostal and long parasternal views have reported a sensitivity and specificity of nearly 100% for the detection of pericardial effusion. Because ultrasound is noninvasive and extremely accurate, its immediate availability in the initial phase of major trauma resuscitation can be very helpful in detecting pericardial fluid before the patient deteriorates hemodynamically.

**Radiography.** The radiographic evaluation of the cardiac silhouette in acute pericardial tamponade generally is not helpful, unless a traumatic pneumopericardium is present. Because small volumes of hemopericardium lead to tamponade in the acute setting, the heart will typically appear normal. This is in contrast to the “water-bottle” appearance of the heart with chronic pericardial effusion. Usually the latter condition is tolerated for a long period.

**Electrocardiography**

Many ECG changes of pericardial tamponade have been described in the literature, but few are diagnostic, and each is more likely to be seen with chronic rather than acute tamponade. For example, electrical alternans (in which the morphology and amplitude of the P, QRS, and ST-T waves in any single lead alternate in every other beat [Fig. 38.18]) has been reported to be a highly specific marker of pericardial tamponade. The postulated cause is the mechanical oscillation of the heart in the pericardial fluid, which is called the swinging heart phenomenon. Echocardiographic
studies have revealed that when fluid accumulates to a critical extent, the frequency of cardiac oscillation may abruptly decrease to half the heart rate. The cardiac position will alternate, with the heart returning to its original position with every other beat, and thus electrical alternans may be seen. Electrical alternans, when present, is pathognomonic for tamponade. However, it is much more common in chronic pericardial effusions that evolve into a tamponade, and it is rarely seen in acute pericardial tamponade. Notably, however, low amplitude of the QRS complexes may be seen as a result of the presence of pericardial effusion.

Management

Field treatment for cases of pericardial tamponade is essentially the same as that outlined for any victim of major trauma. The diagnosis of tamponade should be suspected by the location of penetrating wounds or by the patient’s poor response to vigorous volume resuscitation. Tension pneumothorax, which is much more common, mimics certain aspects of acute pericardial tamponade. If the patient is in extremis or the clinical condition rapidly deteriorates, consideration should be given to performing a needle thoracostomy, which, if not therapeutic, suggests pericardial tamponade in the appropriate clinical presentation by virtue of “diagnosis of exclusion.” Expedient transport to the nearest trauma center should be paramount.

Upon ED arrival, volume expansion with crystalloid solution via two or three large-bore (14- or 16-gauge) catheters should be established immediately. The presence of a pneumothorax or hemothorax, which is often associated with penetrating cardiac trauma, is treated expeditiously with tube thoracostomy. Bedside echocardiography should be performed as quickly as possible to establish the diagnosis of pericardial tamponade, which then should be followed by emergent surgical repair.

There is increasing controversy regarding the role of pericardiocentesis. In the past, it was recommended that pericardiocentesis be performed for both diagnostic and therapeutic reasons. Aspiration of as little as 5 to 10 mL of blood may result in dramatic clinical improvement. However, it should be emphasized that pericardiocentesis is not a benign or invariably successful procedure. Blood in the pericardial space tends to be clotted, and aspiration may not be possible. Possible complications include the production of pericardial tamponade, the laceration of coronary artery or lung, and induction of cardiac dysrhythmias. Whenever possible, pericardiocentesis should be performed under sonographic guidance, because this approach will increase the success rate and decrease the incidence of complications. A pigtail catheter may be introduced into the pericardial space for repeated aspirations while preparations are underway to quickly transport the patient to the operating room for definitive therapy. If pericardiocentesis is unsuccessful or the clinical status deteriorates, and if acute pericardial tamponade remains important in the differential diagnosis, thoracotomy should be performed as quickly as possible. Patients with penetrating cardiac injury invariably require surgical repair. The location (operating room vs. ED) and timing (immediate vs. urgent) depend on the patient’s clinical status.

Emergency Department Thoracotomy

EDT is a drastic, dramatic, and potentially lifesaving procedure in which emergency clinicians should be proficient. Although the procedure is not described in detail here, a few technical points merit discussion. A left lateral incision is preferred because it is rapidly accomplished; allows the best exposure of the heart, aorta, and left hilum; and facilitates open cardiac massage and internal defibrillation (Fig. 38.19). With right-sided or multiple injuries, it may be necessary to extend the incision across the sternum and right chest wall, creating a “clamshell” incision. The internal mammary arteries need to be ligated if this maneuver restores effective perfusion. After the heart is sufficiently exposed, the pericardium is vertically incised anterior to the phrenic nerve. Release of a tamponade may rapidly restore cardiac output. The heart is then delivered through the pericardium, and penetrating wounds are identified.

There are several alternatives for repairing cardiac wounds. Small wounds can be compressed by digital pressure to control bleeding en route to the operating room. If the injury is quite large, balloon tamponade can be achieved by applying gentle traction on a Foley catheter inserted into the wound with the balloon inflated with saline. This can temporarily stop the hemorrhage to allow suture repair of the injury (cardiorrhaphy) or to gain time while the patient is transferred to the operating room.
for a more definitive surgical procedure. Lacerations of the atria can be temporarily controlled with a vascular clamp.

Suture of cardiac wounds over pledgets is the time-honored and effective technique but is technically more difficult and more time-consuming. The use of a monofilament suture, such as 2-0 Prolene, is recommended. Some trauma surgeons recommend stapling cardiac wounds with standard skin staplers because this technique may be much quicker and equally effective in closing these wounds.

Care is taken to avoid ligating coronary arteries during the repair. Direct insertion of a large-bore catheter (eg, a 5-French catheter) into the left atrial appendage provides a route for rapid infusion of fluids. If the heart is empty or the patient fails to respond to rapid fluid administration, the aorta is cross-clamped to divert cardiac output to the brain and heart. Prolonged ischemia and severe acidosis often result in post-resuscitation myocardial depression with ineffective contraction and diminished cardiac output. Thus the cross-clamp should be temporarily released every 30 to 60 minutes to minimize ischemic complications.

**Indications for Emergency Department Thoracotomy.** Although it is often tempting to perform EDT on all traumatic arrest victims in the ED, there are many cases in which patients have virtually no chance of survival. In addition, EDT is costly; requires the undivided attention of all personnel in the ED, diverting care from other, more salvageable patients in critical condition; and poses a risk to ED personnel for injury from needle sticks and other blood-contaminated exposures.

Evidence-based guidelines from the Eastern Association for the Surgery of Trauma recommend that EDT be performed on patients who lose pulses but who initially presented to the ED with signs of life after *penetrating* thoracic trauma (see Box 38.4). They conditionally recommend EDT for both patients who present to the ED without signs of life after *penetrating* thoracic trauma and patients who present to the ED with signs of life after *blunt* injury, and recommend against EDT in patients who sustain *blunt* injury and present to the ED pulseless. It is worth emphasizing that EDT is a temporizing measure and should only be performed if definitive treatment is a viable option in the setting to which the patient presents.

**BLUNT AORTIC INJURY**

**Principles**

**Background and Importance**

Blunt aortic injury is a life-threatening injury, usually resulting from sudden deceleration, usually from automobile crashes. Other mechanisms of injury include pedestrians struck by automobiles, motorcycle crashes, airplane crashes, and falls from heights. Despite the improvement in and increased use of restraint systems, the overall incidence of blunt aortic injury associated with fatal automobile crashes has remained unchanged over the past decade.

Blunt aortic injury includes a spectrum of lesions, ranging from a small intimal tear to frank rupture, which usually causes rapid lethal hemorrhage. The most common sites of injury are the aortic isthmus and the ascending aorta just proximal to the origin of the brachiocephalic vessels. Sixty percent to 90% of patients with blunt aortic injury die at the site of accident or within hours of hospital admission. However, an increasing number of patients arrive at a treatment facility because of improvements in out-of-hospital care, more appropriate resuscitation in the field, and rapid transportation to a trauma center. The early survival rate of such patients depends on the initial resuscitation and/or the timeliness and correct choice of diagnostic procedures. A rapid and accurate diagnosis is thus mandatory to optimize treatment and maximize odds of survival.

**Pathophysiology**

The descending thoracic aorta is relatively fixed and immobile because of its tethering by intercostal arteries and the ligamentum arteriosum. With sudden deceleration, the more mobile aortic arch swings forward, producing a shearing force or “whiplash effect” on the aorta at the isthmus. A bending stress at the isthmus, created by sudden lateral oblique chest compression, may also result in rupture by causing flexion of the aortic arch on the left mainstem bronchus and the pulmonary artery. Forces created by the whiplash effect or lateral oblique compression may not be sufficient to provoke aortic tears. It is now postulated that those injuries may be caused by inferior and posterior rotation of anterior thoracic osseous structures (manubrium, first rib, and medial clavicles), pinching and shearing the interposed aorta as they strike the vertebral column.

Rupture of the ascending aorta just distal to the aortic valve likely occurs through a different mechanism. At the time of rapid deceleration and chest compression, the heart is displaced into the left posterior chest, which causes a shearing stress just above the aortic valve. A sudden increase in intra-aortic pressure, “the water hammer effect,” may cause an explosive rupture of the aorta at this location. Involvement of the coronary ostia with coronary artery occlusion may occur in association with tears to the ascending arch. The intraluminal pressure tolerance of the aorta may be exceeded in a high-speed MVC.

A total of 80% to 90% of aortic tears occur in the descending aorta at the isthmus, just distal to the left subclavian artery (Fig. 38.20). Less common sites of involvement are the ascending aorta, the distal descending aorta at the level of the diaphragm, the midthoracic descending aorta, and the origin of the left subclavian artery. Although ruptures of the ascending aorta are much less common than those of the descending aorta, they have a 70% to 80% incidence of associated lethal cardiac injuries. This is in contrast to ruptures at the isthmus, which have a 25% incidence of associated cardiac injuries. Lethal cardiac injuries commonly
include pericardial tamponade, aortic valve tears, myocardial contusion, or coronary artery injuries. Passenger ejection, pedestrian impact, severe falls, and crush injuries commonly result in ascending thoracic aortic ruptures. Survival long enough to be evaluated in the ED is rare among patients who sustain an ascending aortic rupture.

Aortic rupture may occur from causes other than high-speed MVC deceleration. Rupture has been documented as a complication of external cardiac massage and has been known to occur after fracture-dislocations of the thoracic spine, presumably as a result of direct shearing force. Vertical deceleration injuries resulting from falls can cause a rupture of the ascending aorta by producing an acute lengthening of the ascending aorta. This is the likely mechanism responsible for aortic rupture in the setting of airplane and elevator accidents. Direct kicks by animals, crush injuries, sudden burial by landslide, and air bag deployment have also been reported as causes of aortic rupture. Direct compression of the compliant thorax has been postulated to contribute to aortic rupture in children. Displaced fractures of the sternum, ribs, and clavicle have also been shown to directly lacerate the aorta.

Clinical Features

The possibility of aortic disruption should be considered in every patient who sustains a severe deceleration injury, because approximately 30% of surviving patients with blunt aortic injury will die within the first 24 hours without treatment. This is especially true if the automobile was moving in excess of 45 mph or if there is evidence of severe blunt force to the chest (eg, from a damaged steering wheel). In the case of any moderate- or high-speed MVC, it is imperative that paramedics carefully evaluate the extent of damage to the vehicle, the complaints of the victims, and the physical manifestations of blunt chest trauma. This information should be promptly relayed to the emergency clinician.

Despite the severe nature of the injury, the clinical manifestations of an aortic rupture are often deceptively meager. Associated pulmonary, neurologic, orthopedic, facial, and abdominal injuries are commonly present. Coexisting injuries can mask the signs and symptoms of an aortic injury or divert the physician's attention away from the more lethal aortic rupture. The absence of any external evidence of a chest injury does not eliminate the possibility of an aortic tear. One-third to one-half of patients reported in the literature have no external signs of chest trauma.

The most common symptom is interscapular or retrosternal pain. It is often found in nontraumatic aortic dissection but is present in only 25% of patients with a traumatic aortic disruption. Other symptoms described in the literature but uncommonly present include dyspnea resulting from tracheal compression and deviation, stridor or hoarseness caused by compression of the laryngeal nerve, dysphagia caused by esophageal compression, and extremity pain caused by ischemia from decreased arterial flow.

Clinical signs are uncommon and nonspecific. Generalized hypertension, when present, may be an important clinical sign. Sympathetic afferent nerve fibers, located in the area of the aortic isthmus, are capable of causing reflex hypertension as a response to a stretching stimulus. The presence of a harsh systolic murmur over the precordium or posterior interscapular area may be heard in up to one-third of patients. The murmur is thought to result from the turbulent flow across the area of transection. A less common finding is a swelling at the base of the neck caused by the extravasation of blood from the mediastinum, which results in an increased neck circumference or a pulsatile neck mass. Other clinical signs suggestive of aortic rupture include lower extremity pulse deficit and lower extremity paralysis. Initial chest tube placement output in excess of 750 mL is also suggestive of aortic rupture, especially if the hemothorax is left sided. However, the physical examination is neither sensitive nor specific for aortic injury.

Diagnostic Testing

Chest Radiography

Radiography of the chest can be a valuable tool when aortic rupture is suspected. An increase in the width of the superior mediastinum is the most sensitive sign and is found in the majority of aortic ruptures (Fig. 38.21).

However, specificity of this radiologic sign may be as low as 10%; mediastinal widening may be caused by venous bleeding from a clavicle, thoracic spine, or sternal fracture; pulmonary contusions; a previous mediastinal mass; a misplaced CVP catheter; or magnification caused by the anteroposterior and supine position of a portable chest radiograph. Hence the sign is not pathognomonic for aortic rupture. Every effort should be made to obtain a standard upright inspiratory posteroanterior film, if clinically feasible, before a mediastinum is declared abnormal, to avoid false-positive interpretations. However, although mediastinal widening may be indicative of aortic rupture, its absence does not preclude the injury. Up to nearly half of patients with blunt aortic injury may have a normal mediastinum on chest radiography. Given this, we recommend the use of chest CT scanning in patients with suspected aortic rupture, regardless of x-ray findings.

Chest Computed Tomography Scan

Chest CT scanning is the gold standard test for blunt aortic injury and has replaced aortography as the test of choice. CT scans have almost 100% sensitivity and specificity for rapidly detecting aortic injury while requiring only IV contrast administration (Figs. 38.22 and 38.23). A normal aortic contour on CT, even in the presence of a mediastinal hematoma, has been shown to be highly accurate in excluding thoracic aortic disruption (Figs. 38.24 and 38.25).

As a result of the improvements in CT scanning technology, more subtle aortic lesions are now being identified, which has led to the term “minimal aortic injury.” A minimal aortic injury is defined as an aortic injury with an intimal flap less than 1 cm, and no or minimal periaortic mediastinal hematoma. Up to 10% of patients with blunt aortic injury diagnosed on CT scan may have

![Fig. 38.21. Anteroposterior radiograph of the chest showing wide mediastinum (arrows).](image-url)
depends on the nature of associated injuries. Endovascular or surgical repair of the aortic rupture should be delayed in the presence of life-threatening intracranial or intra-abdominal injury or profuse retroperitoneal hemorrhage. Consideration for delay of the procedure should be made for patients at high risk for infection (eg, those who have extensive body surface burns, contaminated large open wounds, established sepsis, or severe respiratory insufficiency caused by thoracic trauma). Careful regulation of blood pressure is mandatory until definitive surgical repair can be performed. If operative repair is delayed, the systolic blood pressure should be maintained between 100 and 120 mm Hg. The objective of lowering the blood pressure is to decrease the shearing jet effect of an elevated pulse pressure, thus decreasing the possibility of continued adventitial dissection and subsequent free rupture.

Esmolol, a short-acting titratable beta-blocker, is ideally suited for this purpose because, unlike nitroprusside sodium, it decreases the pulse pressure and minimizes the shearing effect on the intact adventitia of the aorta. Esmolol can be initiated with a bolus of 0.5 mg/kg over 1 minute, followed by an infusion of 0.05 mg/kg/min (titrated upward in 0.05 mg/kg/min increments to a maximum of 0.3 mg/kg/min). If blood pressure is not adequately controlled, nitroprusside sodium can be added as a second agent, beginning at a dose of 0.25 to 0.5 mcg/kg per minute.

**Definitive Management**

Many surgical techniques have been described since the first successful repair by Passaro and Pace in 1959. The pathologic condition found dictates the type of repair, and a synthetic graft is often required because of extensive tension on the vessel walls or jagged torn ends of the vessel. However, open repair can have associated complications of stroke, paraplegia, and renal failure due to aortic clamp time.

**Endovascular Repair.** A number of studies indicate that success rates and complication rates are likely better than those of traditional open surgical repairs and that the risk of major surgery and subsequent paraplegia from prolonged aortic clamping is significantly reduced with endovascular repair. Current
guidelines recommend endovascular treatment for patients without contraindications.40

ESOPHAGEAL PERFORATION

PRINCIPLES

Background and Importance

The classic description of esophageal perforation resulting from forceful vomiting was published in 1724 by Boerhaave, and from 1724 to 1941 the occurrence of Boerhaave's syndrome was almost uniformly fatal.47 In 1941 the first successful surgical treatment, a drainage procedure, was reported, and in 1947 the first successful closure of a ruptured esophagus was described. Since then, improved surgical techniques, greater physician awareness leading to a more prompt diagnosis, the availability of more effective antibiotics, and better general supportive measures have reduced the mortality to approximately 20%. Mortality data cited for perforation are affected by several variables, such as location (with perforations of the thoracic segment having the highest mortality rate), mechanism of injury, time elapsed between injury and diagnosis, the presence of preexisting esophageal disease, and general health of the patient.

Pathophysiology

The anatomic feature responsible for the prolonged morbidity and high mortality associated with esophageal perforation is the lack of an esophageal serosal covering that allows perforation at any level direct access to the mediastinum. Perforations in the upper or cervical esophagus enter the retropharyngeal space, where fascial planes extend from the base of the skull to the bifurcation of the trachea. Perforations in the midesophagus and lower esophagus enter directly into the mediastinum. Only the thin mediastinal pleura prevents free access to the entire pleural cavity, and this barrier is commonly overcome by continued drainage and the massive exudative inflammatory reaction induced by chemical and bacterial mediastinitis. When the mediastinal pleura are penetrated, the negative pressure generated by respiratory efforts tends to increase soilage by promoting drainage from the gastrointestinal tract into the mediastinum and pleural space.

When esophageal rupture results from forceful emesis, as in cases of Boerhaave's syndrome, the intrinsic weakness of the left posterior distal esophagus is important. Other areas (including cervical, midthoracic, and infradiaphragmatic sites) have been reported only rarely to rupture secondary to emesis. In addition, the esophagus has three areas of anatomic narrowing: (1) the cricopharyngeal muscle near the esophageal introitus, (2) the level at which the esophagus crosses the left mainstem bronchus and the aortic arch, and (3) the gastroesophageal junction. In the absence of a preexisting esophageal disease (such as, carcinoma), it is unusual for a perforation caused by a foreign body to occur anywhere other than at these three sites. Foreign bodies may cause perforation by direct penetration, pressure, or chemical necrosis.

CLINICAL FEATURES

The most reliable symptom of an esophageal injury is pleuritic pain localized along the course of the esophagus that is exacerbated by swallowing or neck flexion (Fig. 38.26). Pain may be located in the epigastrium, substernal area, or back; usually worsens over time; and may migrate from the upper abdomen to the chest. As the infectious process worsens, dyspnea usually ensues.

The early physical signs of an esophageal perforation are sparse. As air and caustic contaminated material move through the esophageal tear into the mediastinum and pleural space, and before any subcutaneous air is palpable at the root of the neck, the mediastinal air may impart a nasal quality to the voice. Mediastinal air may surround the heart and produce a systolic

Fig. 38.26. A, Chest radiograph of a 36-year-old man with acute onset of pleuritic chest pain after forceful vomiting. B, Chest radiograph shows mediastinal and subcutaneous air typical of ruptured esophagus. Mediastinum is not yet widened, and there is no soilage of the pleural cavity.
BOX 38.5

Most Common Causes of Esophageal Perforation

Iatrogenic
Foreign bodies
Caustic burns
Blunt or penetrating trauma
Spontaneous rupture (post emetic or Boerhaave’s syndrome)
Postoperative rupture of anastomosis

Iatrogenic

Most esophageal perforations are iatrogenic, most commonly as a complication of instrumentation. The rigid endoscope is the most common offender, particularly when general anesthesia is used. Although use of the flexible endoscope has made this complication less likely, the total number of perforations has increased as more procedures are performed. Injuries tend to occur near the cervical esophagus as the endoscope is inserted. Endoscopic procedures that are too vigorous in the presence of a corrosive burn or carcinoma are also a common cause of iatrogenic esophageal injury. In the ED, nasotracheal or nasogastric intubations are the most common causes of iatrogenic perforation, with the perforation usually occurring in the pyriform sinus.

The use of an esophageal obturator airway was also associated with occasional esophageal trauma, specifically midesophageal perforation. Use of the esophageal obturator airway’s successors, the laryngotracheal Combitube and the King airway, do not seem to be associated with trauma more severe than occasional esophageal abrasions or contusions.

Foreign Bodies

Foreign bodies can cause an esophageal injury by direct laceration, by pressure necrosis, or during endoscopic removal. Small perforations tend to seal without sequelae, but pressure necrosis or lacerating injuries provide ample access to the mediastinum. Foreign bodies usually lodge in the cervical esophagus. In children younger than 4 years old, the cricopharyngeal narrowing is the usual point of foreign body impaction. After 4 years old, most objects pass this region and traverse the remaining normal esophagus. In adults, a foreign body impaction, especially in cases of repeated episodes, raises the possibility of a stricture and warrants further investigation.

Caustic Burns

Caustic burns of the esophagus occur from intentional or accidental ingestion of acid or alkali. There are two peaks of incidence: (1) from 1 to 5 years old, which is when ingestion is usually of a small amount of material and accidental, and (2) in the teens and 20s, when larger quantities are ingested during suicide attempts. Symptoms include hematemesis, respiratory distress, vomiting, drooling, or the presence of oropharyngeal lesions on physical examination.

The liquefaction necrosis classically resulting from strong alkali burns (pH >12) is more likely to cause esophageal perforation than the coagulation necrosis resulting from strong acid burns (pH <2). Individuals ingesting alkali substances with a pH less than 11.5 rarely sustain injuries more serious than superficial mucosal burns. Acid ingestions cause damage more frequently in the stomach than in the esophagus.

Endoscopy within the first 6 to 18 hours may be used to determine the extent of the injury and to guide therapy. Although admission after significant ingestion is the rule, some authors suggest that in the setting of accidental ingestion in children and in the absence of symptoms, endoscopy and admission may not be indicated. Esophagoscopy is commonly undertaken to ascertain the presence or absence of esophageal injury. Advancing the esophagoscope beyond the first burn in the esophagus increases the risk of perforation and is a common iatrogenic cause of esophageal perforation.

Penetrating and Blunt Trauma

Because of its well-protected position posteriorly, esophageal trauma is rare and usually not an isolated injury. Cervical esophageal injuries are the most common because of a lack of protection by the bony thorax, and the trachea is the most common associated site of injury. In some cases, the esophageal injury may be overlooked initially because of the dramatic presentation of a patient with a tracheal injury.

Typical symptoms seen in cervical esophageal injuries include neck pain, dysphagia, cough, voice changes, and hematemesis. Physical findings may include neck tenderness, resistance to flexion, crepitus, or stridor. In one large series, the most common life-threatening problem in the ED was compromise of the airway. Most of these cases were handled with rapid sequence intubation, but a significant number (12%) of patients required cricothyroidotomy.

If the patient’s condition is stable, a preoperative esophagram with a water-soluble agent should precede any endoscopy. Although chest and neck radiograph and CT also may be used to diagnose this injury, emergent bedside flexible endoscopy seems to be the test of choice to confirm negative findings on esophagoscopy (especially in the setting of penetrating trauma). Operative repair is indicated in most of these injuries (>90%) and should be done as quickly as possible to avoid the development of fistulae, mediastinitis, or abscess formation.

Spontaneous Rupture

Spontaneous esophageal rupture, post-emetic rupture, and Boerhaave’s syndrome are synonymous terms. This esophageal injury is associated with a poor prognosis because the forces required to rupture the esophagus result in almost instantaneous and massive mediastinal contamination. The distal esophagus is the usual site of injury, with a longitudinal tear occurring in the left posterolateral aspect. More than 80% of these injuries occur in middle-aged men who have ingested alcohol and large meals. Increases in intra-abdominal pressure resulting from blunt trauma, seizures, childbirth, laughing, straining at stool, and heavy lifting have all been reported to cause this injury.

DIAGNOSTIC TESTING

The diagnosis of esophageal perforation is aided by consideration of clinical circumstances. In patients with classic Boerhaave’s syndrome, emesis is followed by severe chest pain, subcutaneous emphysema, and cardiopulmonary collapse. Development
of these signs and symptoms after instrumentation of the esophagus or removal of an esophageal foreign body is relatively straightforward. One-third of cases of perforated esophagus are atypical, however. A careful history and physical examination supplemented by appropriate imaging studies enable the clinician to diagnose a subtle case at an early stage. In considering any of the diagnoses listed in Box 38.6, a perforated esophagus should also be considered.

**Radiology**

The radiographic examination usually suggests the diagnosis of an esophageal perforation. The classic chest radiograph findings are mediastinal air (with or without subcutaneous emphysema), left-sided pleural effusion, pneumothorax, and widened mediastinum. Lateral views of the cervical spine may reveal air or fluid in the retropharyngeal area that is characteristic of a cervical esophageal perforation but also is found when perforations in the lower parts of the esophagus release air or fluid that dissects superiorly (Fig. 38.27). Water soluble diatrizoate meglumine (Gastrografin) is preferred for visualization in cases of suspected esophageal perforation. It does not obscure visualization during subsequent endoscopy, and it produces less mediastinal soiling than barium. Then, if no leak is found, a barium study may be undertaken to better define the mucosal detail.

**Endoscopy**

Endoscopy, similar to contrast studies, is not an infallible aid in establishing the presence or absence of an esophageal perforation. The size and location of the perforation and the skill of the endoscopist are important factors in the low incidence of false-negative studies. If the accuracy of the endoscopy is in doubt, an esophagogram should be performed. Helical CT with dilute oral contrast has been reported as a safer, faster, and less manpower-intensive diagnostic examination. Some of the abnormalities that may be seen on CT scan include extraluminal air, periesophageal fluid, esophageal thickening, and extraluminal contrast. These CT findings may be the first clue to the correct diagnosis of esophageal perforation.

**MANAGEMENT**

Early diagnosis can best be accomplished if one is aware of the pathophysiology and clinical settings in which esophageal perforations occur. Time is crucial in minimizing the mortality and morbidity of this condition. If the diagnosis is strongly suggested or confirmed, management should include broad-spectrum antibiotics (covering oral flora), volume replacement, and airway maintenance.48 An emergency surgical consultation should be obtained because prognosis worsens as time passes, with mortality almost doubling in the first 12 hours.

Although operative therapy is standard, nonoperative therapy is an option for patients with well-contained perforations, with minimal mediastinal involvement, and without evidence of sepsis. In such cases, the patient is placed on nil per os (nothing by mouth) (NPO) status for at least 72 hours, broad-spectrum antibiotics are initiated, and usually total parenteral nutrition treatment is begun. The use of nasogastric tubes should be discouraged, because they may increase gastroesophageal reflux and worsen the contamination of the mediastinum.

**KEY CONCEPTS**

- Even relatively minor chest wall injuries, such as rib fractures, may result in serious complications in elderly patients and patients with preexisting pulmonary disease if adequate analgesia and close follow-up care are not provided.
- Unless there are abnormalities on the electrocardiogram (ECG) or an elevated serum troponin level, there is no need to pursue the diagnosis of myocardial contusion with more sophisticated tests.
- Many patients with myocardial rupture or traumatic aortic rupture survive to reach the hospital and can be salvaged with rapid diagnosis and intervention.
- Pericardial tamponade can be diagnosed accurately before hemodynamic decompensation occurs by standard cardiac ultrasound performed by emergency clinicians.
- Chest computed tomography (CT) scan is the test of choice for blunt aortic injury even in the presence of normal chest radiographs.
- The NEXUS-Chest CT criteria can be used to determine the need for chest CT in patients with blunt trauma.

CHAPTER 38: Thoracic Trauma

38.1. An 18-year-old man presents after a motor vehicle collision (MVC) in which he was ejected from the vehicle. The paramedics have been administering bag-valve-mask ventilation en route because of respiratory distress and now report increased resistance with ventilations. The patient has decreased breath sounds on the left. His blood pressure is 80/40 mm Hg, and his pulse is 145 beats per minute. His respirations are agonal, with a rate of 5 breaths per minute. Which of the following is the most appropriate next step in the management of this patient?

A. Anteroposterior chest radiograph
B. Emergency department thoracotomy (EDT)

Endotracheal intubation
D. Needle decompression
E. Tube thoracotomy

Answer: D. This clinical scenario depicts a patient with a tension pneumothorax. He has decreased blood pressure, decreased breath sounds, and, most important, an increased resistance to ventilation, which is the earliest sign of the development of a tension pneumothorax. Immediate decompression with a large-bore needle is the correct initial management in this condition.
38.2. Which of the following is the most sensitive electrocardiogram (ECG) manifestation of myocardial contusion?
A. Biphasic T wave
B. Left bundle branch block
C. Right bundle branch block
D. Sinus tachycardia
E. Transient ST segment elevation

Answer: D. Sinus tachycardia is present in approximately 70% of patients with documented myocardial contusion and is the most sensitive sign for this condition. It is, however, also the least specific.

38.3. A patient presenting with blunt thoracic trauma complains of shortness of breath and chest pain. On physical examination, he is tachypneic with chest wall bruising and moist rales on the right side on auscultation. Which of the following is the least likely finding?
A. Consolidation within 6 hours of injury
B. Diffuse patchy alveolar infiltrates on chest radiograph in 24 hours
C. Low partial arterial pressure of oxygen (PaO₂) on arterial blood gas sampling
D. Patchy alveolar infiltrate on chest radiograph within minutes of injury
E. Rib fractures

Answer: B. This patient has physical findings consistent with pulmonary contusion. All answers are correct except B. Delayed onset of diffuse alveolar infiltrates is more consistent with acute respiratory disease syndrome (ARDS). The development of ARDS is diffuse and usually delayed, with onset typically between 24 and 72 hours after injury.

38.4. A 55-year-old man complains of chest wall pain after a high-speed motor vehicle collision (MVC). He has ecchymosis of the left lateral chest wall. You notice that there is outward movement of the left lateral chest wall on expiration. Which of the following statements regarding this patient's problem is not true?
A. Chest radiograph likely demonstrates parenchymal contusions.
B. Intubation splints the chest wall internally.
C. Multiple rib fractures are likely.
D. Positioning of patient with injured side down improves symptoms.
E. The cornerstone of treatment is pulmonary physiotherapy.

Answer: D. This patient has a flail chest. Out-of-hospital or emergency department (ED) stabilization of the flail segment, by positioning the person with the injured side down or placing a sandbag on the affected segments, has been abandoned. Endotracheal intubation and positive-pressure ventilation will internally splint the chest wall, making the flail segment difficult to detect on physical examination. The cornerstones of therapy include pulmonary physiotherapy, effective analgesia, selective use of endotracheal intubation and mechanical ventilation, and close observation for respiratory compromise.

38.5. A 50-year-old woman is brought in by emergency medical services on a backboard after a motor vehicle collision (MVC), complaining of shortness of breath. She has decreased breath sounds on the right side of the chest. A chest tube is placed, with a return of 200 mL of blood in the first hour, 200 mL in the second hour, and 350 mL in the third hour. What is the next step in the management of this patient?
A. Check coagulation profile
B. Conservative management and transfusion as needed
C. Emergency thoracotomy
D. External fixation of rib fractures
E. Insertion of a second thoracostomy tube

Answer: C. Immediate drainage of more than 1500 mL of blood from the pleural cavity is usually considered an indication for urgent thoracotomy. Perhaps even more predictive of the need for thoracotomy is a continued output of at least 200 mL/hr for 3 hours.

38.6. A 37-year-old man presents with chest pain after a motor vehicle collision (MVC). He states that his chest hit the steering wheel. On initial evaluation, the patient is hypotensive after a front-end collision. She was the driver and unbelted. Despite fluid resuscitation, the patient continues to be tachycardic and hypotensive.

A. Which of the following is the most sensitive sign for this condition? It is, however, also the least specific.
B. Immediate drainage of more than 1500 mL of blood from the pleural cavity is usually considered an indication for urgent thoracotomy. Perhaps even more predictive of the need for thoracotomy is a continued output of at least 200 mL/hr for 3 hours.
C. A 30-year-old woman presents intubated by emergency medical services on a backboard with C spine immobilization. She was found unresponsive and hypotensive after a front-end collision. She was the driver of the vehicle and unbelted. Despite fluid resuscitation, the patient continues to be tachycardic and hypotensive.
D. Insertion of a second thoracostomy tube
E. The cornerstone of treatment is pulmonary physiotherapy.

Answer: B. In patients who have minor injuries and are otherwise asymptomatic, elevated troponin levels and minor ECG abnormalities do not necessarily indicate a clinically significant myocardial contusion. Very few of these patients will develop complications. However, normal troponin level (4 to 6 hours after injury), along with normal (or unchanged) ECGs, correlate with minimal risk of cardiac complications. Echocardiography is rarely required in this low-risk subset of patients who have minor injuries and are otherwise asymptomatic.

38.7. A 30-year-old woman presents intubated by emergency medical services on a backboard with C spine immobilization. She was found unresponsive and hypotensive after a front-end collision. She was the driver of the vehicle and unbelted. Despite fluid resuscitation, the patient continues to be tachycardic and hypotensive.

A. Early use of emergency department (ED) ultrasonography may facilitate the early diagnosis of cardiac rupture and pericardial tamponade. The combination of shock and JVD (or an elevated central venous pressure [CVP]) in a patient with blunt chest trauma should immediately suggest pericardial tamponade.
Abdominal Trauma

James R. Nichols III | Michael A. Puskarich

CHAPTER 39

PRINCIPLES

Background

The management of abdominal trauma relies on applying knowledge and organization to key clinical features and the timely use of diagnostic procedures. Advancements in imaging have helped to decrease missed or delayed diagnoses, yet abdominal injuries can be notoriously occult, requiring both diligence and vigilance to achieve the best outcomes.

Penetrating Abdominal Trauma

Whether by accident or intention, penetrating trauma can result from a wide variety of weapons or instruments, and certain elements of therapy vary accordingly. The careful integration of physical examination and certain diagnostic procedures, notably local wound exploration (LWE), ultrasonography, computed tomography (CT), laparoscopy, and in rare instances, diagnostic peritoneal tap (DPT), now provides an accurate and reliable means of determining whether laparotomy should be undertaken. The approach varies according to the clinical status of the patient, the instrument responsible for injury, and the site of penetration. Nonoperative management has gained favor predominantly for stab wounds, though also for carefully selected gunshot wounds, with the intent to reduce the incidence of and morbidity from nontherapeutic laparotomies.

Wounds from stabbing implements occur nearly three times more often than from firearms, but the latter are responsible for 90% of penetrating trauma mortality. The small intestine, colon, and liver are the most likely organs to sustain injury after penetrating trauma. The highest risk of death from penetrating abdominal injury occurs among African Americans in the 15- to 34-year-old age range, followed by Hispanic persons in that same age group. The rate for non-Hispanic whites is greatest at 75 years of age and older. The predominant intent is homicide among African Americans and suicide among non-Hispanic whites.

The use of firearms in the United States contributes heavily to the morbidity and mortality of trauma. The number of homicides committed with firearms exceeds the number of homicides resulting from all other forms of violence combined. More than 850,000 American civilians were killed by bullets in the 20th century. Please see Chapter e2 for a more complete discussion of injury prevention.

Blunt Abdominal Trauma

Despite advances in imaging, blunt injuries carry a greater risk of mortality than penetrating injuries because they are more difficult to diagnose and are commonly associated with severe trauma to multiple intraperitoneal organs and extra-abdominal systems. Historical data may be incomplete, absent, or presumptive. The symptoms and signs can be unreliable and obfuscated by head injury, alcohol, or other toxins. The likelihood of extra-abdominal systems trauma adds further complexity, underscoring the need for a carefully organized approach.

The spleen is the organ most often injured; and in nearly two thirds of these cases, it is the only damaged intraperitoneal structure. The liver is the second most commonly injured intra-abdominal organ, and injury to any hollow viscus is uncommon by comparison, with the intestine the most likely hollow viscus to be damaged. Most cases of blunt abdominal trauma are caused by motor vehicle collisions, whereas blows to the abdomen and falls make up a minority of blunt abdominal trauma cases.

Anatomy and Physiology

The abdominal cavity and its contents can be reached not only through the anterior abdominal wall and lower chest but also through the flank, back, and buttocks. Rarely, missiles lodge intraperitoneally after traversing proximal extremities, as well. The anterior abdomen begins at the nipple line or fourth intercostal space anteriorly and extends down to the inferior costal margins. The flank is between the anterior and posterior axillary lines bilaterally from the inferior scapular tip to the iliac crest. The back extends from the posterior axillary lines, beginning at the inferior scapular tip and extending down to the iliac crest. The intraperitoneal cavity is vulnerable when penetration occurs as high as the fourth intercostal space anteriorly and the sixth or seventh laterally and posteriorly because the diaphragm can ascend to this level during expiration. Simultaneous thoracic and abdominal penetration can be found in 20% to 40% of cases of abdominal thoracic trauma. Scrutiny of entrance and exit sites, as well as wound tracts, is imperative.

Pathophysiology

Penetrating Abdominal Trauma

Penetrating abdominal injuries predominantly are caused by knives and firearms. Injuries caused by impalement objects, such as fences, stakes, or similar objects are treated as stab wounds. Various propelled missiles from lawn mowers or other machinery are managed as gunshot wounds, based on their velocity. Fragmentation injuries produced by grenades and bombs are rare in this country, but industrial explosions can produce similar injuries, and blunt abdominal trauma from blast effect can coexist in this setting. Domestic terrorist acts may involve improvised bombs that are loaded with shrapnel, such as BBs, ball bearings, or nails, with penetrating abdominal trauma often the least dramatic of the injuries.

The liver, followed by the small bowel, is the organ most often damaged by stab wounds, in keeping with the location and surface area of these structures. The frequency of organ injury caused by gunshot wounds is greatest for small bowel, followed by the
Stab Wounds. A variety of implements besides knives can induce stab wounds, which occur most commonly in the upper quadrants. Nearly one quarter of cases have multiple wounds, and up to 10% of cases involve the chest. Most stab wounds do not cause an intraperitoneal injury, although the incidence varies with the implement used and the direction of entry. Anterior stab wounds penetrate the peritoneum in approximately 70% of cases but inflect a visceral injury in only half of these. Left lower chest wounds are associated with a 17% incidence of intraperitoneal damage in addition to the high rate of thoracic and diaphragmatic injuries, whereas right lower chest wounds have a much lower incidence of 0% to 4%. Abdominal entries from the flank and back have reported incidences of up to 44% and 15%, respectively. The liver and spleen are the visera most commonly damaged in cases of back and flank wounds, but the injury pattern cannot be well predicted by the site of entry in the abdominal wall.

Gunshot Wounds: Ballistics. The science of ballistics is complex, but a few basic principles are helpful in understanding the pathophysiologic processes. The magnitude of the injury is proportional to the amount of kinetic energy imparted by the bullet to the victim, according to the following equation:

\[ E = \frac{7000 m v^2}{2g} \]

where \( E \) is the kinetic energy (in foot-pounds), \( m \) is the mass of the bullet, \( v \) is the velocity of the bullet (in ft/s), and \( g \) is gravitational acceleration (in ft/s). The degree of injury depends on the mass of the bullet and the square of its velocity, although the resistance and viscoelastic properties of the tissue affect the resultant injury, as well. Missile velocities are categorized as low (slower than 1100 ft/s), medium (1100 to 2000 ft/s), and high (faster than 2000 to 2500 ft/s). Impact velocity is the most important determinant of wounding capability, which depends on the distance between the firearm and the victim, the muzzle velocity, and characteristics of the missile. At medium and high velocities, the missile has an explosive effect and creates a temporary passage in the tissue along its course, directly proportional to the specific gravity of the penetrated tissue. This sudden formation of a tract displaces nearby organs and vascular structures, and bone and viscera may be fractured or torn without being directly struck by the missile. Several cases of an intraperitoneal injury caused by a bullet that remained extraperitoneal throughout its entire course have been reported. Solid viscera, such as the liver and spleen, are more vulnerable to this effect.

High-Velocity Missiles. Wounds from high-velocity missiles involve additional problems. External contaminants tend to be dragged into the wound, high-velocity bullets can fragment internally, and closure of the tract immediately after the bullet’s passage may lead to an underestimation of tissue damage. A missile at any velocity can fragment after contact with bone and cause additional multiple trajectories and injuries, which makes assumptions regarding bullet tracts dangerous in the assessment of the patient. Civilian wounds usually result from low-velocity handguns, but there has been a trend toward more destructive weapons.

Shotgun Wounds. Because of the ballistic shape of the individual pellets, a rapid falloff in velocity occurs, making this weapon ineffective in producing severe wounds at long distances. An initial muzzle velocity of 1300 ft/s drops to 950 ft/s within 20 yards, a decrease of 25%. At close range (<15 yards), however, the shotgun is extremely lethal, which has implications for patient care. Although the kinetic energy depends on the pellet’s size, the number of striking pellets, the type and amount of powder, and the barrel choke (constriction), the most important clinical variable is the distance between the shotgun and the victim. At a distance of 10 yards (9 meters), 19% of the pellets cluster in a 9-inch (23 cm) diameter circle if fired from a full choke (maximum constriction) barrel. At a distance of 20 yards (18 meters), the circle is approximately double that diameter. Because the kinetic energy is proportional to the square of the velocity, a 25% loss of velocity at 20 yards (18 meters) results in a significant decrease in the damage produced by the blast.

Shotgun wounds have been previously classified in three groups according to the range and pattern of distribution. More recently, classification has been according to the pattern of injury on the victim. Based on distance from the weapon to the victim, type I wounds involve a long range (>7 yards or 6.4 m) and a penetration of subcutaneous tissue and deep fascia only. Type II wounds occur at a distance of 3 to 7 yards (2.7 to 6.4 m) and may create a large number of perforated structures. Type III wounds occur at point-blank range (<3 yards or 2.7 m) and involve a massive destruction of tissue. When categorized by pattern, type I wounds produce a spread greater than 25 cm in diameter; type II, 10 to 25 cm in diameter; and type III, less than 10 cm in diameter. Close-range shotgun wounds, in addition to the shot, force external contaminants (eg, clothing and parts of the shell wadding) into the wounds. Type III wounds carry a substantial mortality risk.

Blunt Abdominal Trauma

Sudden and pronounced rises in intra-abdominal pressures created by outward forces, such as lap-belt-only restraints, can cause rupture or burst injury of a hollow organ. Compression of abdominal viscera between the applied force to the anterior wall and the posterior thoracic cage or vertebral column produces a crushing effect. Solid viscera are especially vulnerable to this injury, which is why liver and spleen injury are so common in blunt abdominal trauma. Crush injuries are more likely to occur with the lax abdominal wall characteristics of elderly or intoxicated patients. Finally, acceleration and deceleration cause organs and vascular pedicles to shear at the relatively fixed points of attachment.

Seatbelt Injuries. Unrestrained passengers are at unequivocally greater risk of intra-abdominal injury than their restrained counterparts. The three-point shoulder-lap belt is the most effective restraining system and is associated with the lowest incidence of abdominal injuries. However, abdominal injuries are still ascribed to combined shoulder-lap belt systems. The shoulder belt component can lead to right-sided and left-sided rib fractures for the driver and front seat passenger, respectively, with potential for injury to underlying abdominal viscera, particularly in the case of improper underarm usage of the shoulder belt.

Injuries resulting from solitary lap belts are most often to the abdomen. The pathogenesis is usually the compression of bowel between the belt and the vertebral column, resulting in a contusion or perforation of the intestines or a tear of the mesentery. Approximately one fourth of these patients develop evidence of a hemoperitoneum secondary to mesenteric lacerations. In the remainder, the intestinal injury most commonly involves the jejunum, and the initial signs and symptoms are often absent or considered insignificant. Subsequent delays in diagnosis of up to 8 weeks have rarely been reported. The “seatbelt sign,” contusion or abrasion across the lower abdomen, is found in less than one third of patients with abdominal injuries caused by lap belts. Its presence, however, is highly correlated with intraperitoneal...
PART II  Trauma  |  SECTION ONE  General Concepts and System Injuries

Clinical Features

The patient’s history may be unobtainable, elusive, or temporarily deferred while resuscitative measures are carried out. When the situation permits and a reliable source is available, certain information is valuable. The patient’s ability to relate the course of events may be compromised by head or spinal cord injury, alcohol intoxication, developmental delay, psychiatric illness, and any number of toxins that will affect the clinician’s assessment of the patient. At times, the trauma may have preceded the onset of symptoms by days, weeks, or even years, and may have been forgotten or considered trivial by the patient. This is particularly true of delayed presentation of diaphragmatic hernia related to a prior penetrating lower chest injury. Witnesses at the scene, particularly paramedical personnel, often provide the most reliable data.

Appreciation of comorbid medical conditions, particularly cardiovascular disease and coagulopathies, optimizes fluid and blood component therapy. When a prehospital care team or transferring hospital is involved, the vital signs, physical assessment,prehospital course, and response to therapy should be obtained. Clinical records and laboratory and radiologic studies obtained at an outlying hospital should be carefully reviewed.

Abdominal pain is the most obvious symptom of abdominal trauma. A hematic, infectious, acidic, or enzymatic irritation of the peritoneum produces pain. The pain may be clearly present at the outset or delayed for hours to days. The perception communication of such pain may be dulled or ineffectual, or the perception of pain may be impaired by a spinal cord injury or an underlying medical problems. Occasionally, intense, competing pain at another body site dominates and distracts both the patient and physician away from the abdomen. Abdominal pain can be localized, because it sometimes is in the left upper quadrant with a splenic injury, or diffuse, such as in septic peritonitis subsequent to bowel perforation.

Pain need not be localized to the abdomen, and irritation of the diaphragm by hemoperitoneum can cause referred pain to the right and left shoulder tips or neck, particularly when the patient has been in the Trendelenburg position. This most often is a marker of hepatic or splenic injury. Pain can also be referred to the testicle in the setting of retroperitoneal injury and is seen most commonly with urogenital and duodenal trauma.

A variety of other extraabdominal symptoms may be present as well. If substantial enough, volume loss may produce orthostatic or frank dizziness, light-headedness, and confusion. Nausea and vomiting can accompany peritoneal irritation or hypovole-
not mitigate the need to evaluate the peritoneal cavity. Solitary cranial or spinal injury should not be considered the sole cause of shock until intra-peritoneal injury has been excluded.

In cases of penetrating trauma, inspecting the abdomen for entrance and exit wounds may help determine the path of injury. Distention can occur as a result of hemoperitoneum or pneumoperitoneum, gastric dilation, or ileus secondary to peritoneal irritation. An echymotic discoloration of the flanks (Gray-Turner sign) or umbilicus (Cullen’s sign) indicates retroperitoneal hemorrhage, but these signs are usually delayed for 12 hours to several days. Abdominal contusions can result from various implements; and when caused by lap-seat belts, they herald abdominal injuries in one third of cases. Presence or absence bowel sounds does not reliably identify or exclude the presence of intra-abdominal injury.

Although palpation elicits local or generalized tenderness in the vast majority of alert patients with an intra-abdominal visceral injury, it is less reliable in patients with altered mental status. However, physical examination can be unreliable even in conscious, responsive patients. Local and generalized rebound tenderness and rigidity can be signs of peritoneal irritation but occur less commonly. These signs lack specificity and can be found with lower rib fractures and contusions of the thoracoabdominal wall as well. Rarely, encapsulated bleeding into regions walled off by blood clots or adhesions can form palpable intra-abdominal masses; these usually appear at least several hours later. Severe contusions of the abdominal wall can cause tenderness and voluntary guarding that is localized and usually exacerbated by use of the affected muscle. A palpable mass can represent a rectus hematoma or ventral hernia.

Rectal examination, once a routine part of trauma assessment, rarely, if ever, provides clinical useful information and is not indicated in the vast majority of trauma patients. This is particularly true in conscious patients of both sexes, for whom rectal examination is uncomfortable, unnecessary, and potentially humiliating. The sole remaining value of rectal examination is as part of the neurological assessment (for anal sphincter tone) for patients with spinal injury more likely, their absence does not preclude serious intraperitoneal injury.

Although the presence of physical findings makes intraperitoneal injury more likely, their absence does not preclude serious pathology, and no finding is exclusively diagnostic of a specific injury. Extended observation and the use of certain laboratory procedures greatly help prevent erroneous or missed diagnoses.

Penetrating Abdominal Trauma

Stab Wounds. Serial physical examination performed by the same observer is useful in appropriately staffed and experienced centers, particularly with patients who are alert, communicative, and neurologically intact. The presence of intoxicants does not necessarily preclude reliance on examination but may decrease its value until sobriety is regained. Even among patients with evidence of shock, peritonitis, or evisceration after penetrating trauma to the abdomen exploratory laparotomy fails to reveal intraperitoneal organ injury in over 10% of cases. In contrast, up to one third of patients with significant intra-abdominal injuries have no suggestive physical signs, particularly when a retroperitoneal injury has occurred.

Gunshot Wounds. As with blunt or other modes of penetrating trauma, there are limitations to physical examination of patients with abdominal gunshot wounds. Up to 20% of patients with a documented intraperitoneal injury have no peritoneal signs before exploration, whereas objective physical findings suggestive of intra-abdominal damage may be present in up to 15% of patients in whom laparotomy reveals no injury.

Blunt Abdominal Trauma

Overall, the accuracy of the physical examination in patients with blunt abdominal trauma is only 55% to 65% because the initial presentation may be deceptively benign. The most reliable symptoms and signs in alert patients are pain, tenderness, and peritoneal findings, particularly when risk factors for abdominal injury are present. When altered sensorium intercedes, the physical signs become less reliable. Frequent evaluations by the same examiner are indicated even in alert patients, but especially in sensorium-altered patients, particularly as their mental status and sensorium normalize.

DIFFERENTIAL DIAGNOSES

Trauma Versus Medical Condition

Medical and traumatic pathologic conditions can be coincident or lead one to the other. For instance, hypoglycemia or a generalized convulsive seizure may precipitate a motor vehicle collision, and the patient’s altered mental status may incorrectly be ascribed to closed head injury, delaying diagnosis of the medical condition. Patients with infectious mononucleosis can experience splenic rupture after relatively trivial trauma, and presentation may be delayed. Finally, patients with premorbid coagulopathy or who are on therapeutic anticoagulation may sustain serious intracranial or intra-abdominal hemorrhage from otherwise unimpressive trauma (see Chapters 33 and 34).

Single Versus Multisystem Trauma

Emergency clinicians should be wary and not miss the proverbial forest for the trees. For instance, the pedestrian struck by a car who has an alleged isolated tibial-fibular fracture may well harbor significant intra-abdominal pathology, irrespective of a nontender abdomen.

Single Versus Multiple Intraperitoneal Organ Injury

There has been an increasing trend toward nonoperative management of known intraperitoneal solid organ injury, specifically of the spleen and liver. However, coincident hollow viscus pathologic lesions may exist but not be discernible initially on clinical examination or diagnostic studies. In addition, patients without solid organ pathology who have increasing amounts of free peritoneal fluid or tenderness warrant careful consideration for hollow viscous damage.

Intraperitoneal Injury Versus Necessary Laparotomy

Formerly, suspicion or knowledge of any intraperitoneal injury mandated laparotomy. Now, diagnostic effort is appropriately aimed at determining whether surgery is necessary or whether the injury is self-limited and does not require repair.

DIAGNOSTIC TESTING

Ultrasoundography

Extended focused assessment with sonography for trauma (E-FAST) examination is indicated in all poly-trauma patients and all patients with suspected abdominal injury, whether by blunt or penetrating mechanism. Ultrasoundography’s primary role is detecting free intraperitoneal blood after blunt trauma. This is accomplished by an examination of Morrison’s pouch, the
Laboratory

Hematologic and chemical values are of limited use in the management of the acutely traumatized patient and should be considered adjuncts to diagnosis and not substitutes for clinical assessment. Laboratory assessment for patients with severe or multi-system trauma has historically relied on “trauma panels,” which are a form of standing or automated order of myriad tests, the majority of which are not indicated. Both payers and
evidence-based practice argue strongly for the cessation of this wasteful and often clinically misleading practice. This is particularly true for patients with suspected abdominal trauma. Targeted laboratory evaluation, however, can provide significant guidance in the assessment and management of the traumatized patients.

Hematocrit

The hematocrit reflects baseline value, extent of and time from hemorrhage, exogenous fluid administration, and endogenous plasma refill. The last of these is a physiologic compensatory shift of extracellular fluid into the intravascular space, the intent of which is to restore the original blood volume. Based on a study of volunteers sustaining a 10% to 20% blood loss, this restoration requires over 24 hours for completion. Patients with hemorrhagic shock (at least 40%) demonstrate much faster plasma refill rates, with significant decreases in hematocrit within 90 minutes. Although easily measured, hematocrit is often a conundrum when viewed in isolation, and serial determinations are more helpful.

White Blood Cell Count

The white blood cell (WBC) count has little discriminatory value in cases of abdominal trauma, particularly its acute phase. The WBC count may be normal or may show a modest leukocytosis (12,000 to 20,000/mm³ with or without left shift), which can occur in the setting of multisystem trauma as a result of stress-induced demargination in the absence of any intra-abdominal process, or as a result of tissue injury, acute hemorrhage, or peritoneal irritation.

Chemistry

Although included in many “trauma panels,” neither serum amylase nor lipase is useful in the evaluation of acute abdominal trauma. Normal levels do not exclude a major pancreatic injury, and elevated values may be caused by any of an assortment of reasons in addition to an injured pancreas, including alcohol, drug toxicity, or systemic hypotension and pancreatic hyperperfusion without pancreatic injury. Elevated or rising levels may indicate damage but in themselves are not conclusive. In all cases, clinical examination and status direct further investigation.

Metabolic acidosis in the setting of trauma can suggest the presence of hemorrhagic shock. This can be witnessed chemically as a decreased serum bicarbonate level, increased base deficit, or elevated lactate level. Although normal values do not exclude abdominal injury, abnormalities, such as a base deficit greater than or equal to 6, elevated lactate greater than 4 mmol/L, or increase over time in either of these indices, suggests perfusion compromise or injury. These findings should be considered in clinical context, because the cause of the abnormalities may be extra-abdominal and trending of laboratory findings lags behind the clinical deterioration or improvement of the patient.

Elevated serum transaminases can result from hepatic trauma but do not distinguish minor contusions from severe injury. Alternatively, these may be symptomatic of alcohol-induced liver damage. Elevated liver transaminase levels may be useful for screening pediatric patients for intentional trauma (see Chapter 177).

Screens for ethanol and drugs are often used in trauma centers. Their utility in the management of abdominal trauma, per se, has not been established, particularly in patients with normal mental status. Positive study findings may prompt the emergency clinician to interdict and the patient to decrease the recidivistic use of ethanol or drugs, and physician intervention during this “teachable moment” has been shown to be effective.

Radiology

Resuscitation and initial stabilization measures precede abdominal radiographic studies. The purpose of diagnostic studies is twofold (Table 39.1): to discern or eliminate the presence of hemoperitoneum in the patient whose condition is critical and unstable to properly sequence management and, in less urgent circumstances, to demonstrate organ injury that requires operative repair. Basic plain radiography of the abdomen in the trauma bay is not indicated, except for missile location or identification. Portable chest x-ray examination has been a staple to screen for significant hemothorax or pneumothorax before the patient is transferred to the CT scanner, but this is largely being replaced by

the chest portions of the E-FAST examination, which has proven at least as sensitive and specific as portable chest radiography for both conditions.39

Hemodynamically stable patients who will undergo expeditious abdominopelvic CT can forego pelvic radiographs in the trauma bay. Indications for pelvic radiography are discussed in Chapters 33 and 48. In patients whose evaluation, including E-FAST results, demonstrates likely intra-peritoneal injury requiring laparotomy, delay in operation to obtain further diagnostic radiology studies is permissible only when the patient has been stabilized and only if studies might aid in determining management.

Plain Radiographs

The chest radiograph and anteroposterior pelvic films can be invaluable in some cases of penetrating and blunt trauma, depending on the presentation and results of initial evaluation. Chest radiographs can provide extra-peritoneal causes of hypotension in the unstable patient. Plain abdominal films can demonstrate the location or presumed track of the missile(s) in gunshot and shotgun injury but are of little value in blunt trauma or non-projectile penetrating trauma, particularly if CT imaging of the abdomen is anticipated. If plain radiography of the abdomen is done, the finding of rib, pelvic, vertebral body, or transverse spinous process fractures in the blunt trauma patient warrants special consideration for nearby visceral damage.

Although free intraperitoneal air can be detected on plain films, the small amounts and location of air associated with small bowel injuries are seen more readily on CT. Free intraperitoneal air uncommonly can be generated by mediastinal or pulmonary injury, as well as by barotrauma, and its presence is not pathognomonic of hollow viscus perforation. Intraperitoneal air is mobile; in upright films, air is located under the diaphragm or the central tendon of the diaphragm anteriorly. In supine films, air tracks under peritoneal attachments, such as the falciform ligament and urachus, up to the anterior abdominal wall. On films in which the patient is in a lateral decubitus position, air is located in the superior flank and outlines the lateral liver edge. Extraperitoneal colonic perforations may extravasate air, which outlines the psoas muscle and perinephric region. All of these injuries are much more readily identified and localized on abdominal CT and thus remain the imaging modality of choice.

Foreign bodies and missiles are easily identified on abdominal films. Therefore their absence without a known exit wound warrants further search of other body cavities (eg, the chest, upper thighs, buttocks). A ricochet off the spine or pelvis into the chest or proximal extremities can occur. An entry into the vascular system may carry the object toward and into the right side of the heart or peripherally into the arterial tree. It may also find its way into the gastrointestinal tract and either produce obstruction or pass through unnoticed. Thus, the location of a bullet and its fragments may provide its primary value in suggesting if extraperitoneal injuries are present.

Computed Tomography

CT scanning is the primary diagnostic imaging test for trauma. CT scanning can define the injured organ and the extent of the injury. It is most accurate for solid visceral lesions and discerns the presence, source, and approximate quantity of intraperitoneal hemorrhage (Fig. 39.3). It can demonstrate active bleeding from the liver or spleen and can be used to determine whether observation, therapeutic angiographic embolization, or open operative intervention is indicated. By minimizing the incidence of non-therapeutic laparotomies for self-limited injury to the liver or spleen, it decreases morbidity and cost.10 CT scanning also evaluates the retroperitoneum (Fig. 39.4), an area not sampled by E-FAST, while simultaneously evaluating the vertebral column, and can be readily extended above or below the abdomen to visualize the thorax or pelvis. CT scanning also provides definitive evaluation for most possible injuries to the urinary tract, including renal artery injury.14 It can also detect other vascular hemorrhage and obviate the need for angiography in some patients. Little additional information is provided by the addition of oral contrast, and most trauma centers use intravenous contrast alone, which decreases aspiration risk for the patient.

CT scanning, however, is relatively insensitive for injury of the pancreas, diaphragm, small bowel, and mesentery, although detection of these injuries is improving (Fig. 39.5). The last two are particularly worrisome because coincidental hollow viscus injury in patients with blunt trauma, although uncommon, is not rare, and increased morbidity and death can ensue if diagnosis is missed or the condition goes undetected for a prolonged period. Findings on CT scans, including the suspected quantity of hemoperitoneum or the presence of isolated free fluid, are not able to forecast well the need for operative intervention. Complications
Magnetic Resonance Imaging

Magnetic resonance imaging (MRI) is usually impractical and sometimes impossible to perform in the acute phase of multiple blunt trauma. Currently, in acutely injured trauma patients, MRI should be reserved for the evaluation of spinal cord injuries and elusive diaphragmatic defects not amenable to laparoscopy or thoracoscopy in the fully stabilized patient.

MANAGEMENT

The field approach to multiple or serious trauma focuses on rapid transportation to a capable receiving emergency department (ED) and is discussed in Chapter 33. An emerging body of evidence has evolved around the concept of “permissive hypotension,” where a mild degree of hypotension (mean arterial pressure >50 mm Hg) is tolerated to decrease unnecessary fluid resuscitation, which can worsen trauma-induced coagulopathy, hypothermia, and may increase the risk of destabilizing relatively “soft” clots. Although animal and some human data support this practice, definitive clinical trial evidence mandating the practice is currently lacking.

In the ED, assessment of abdominal injury is part of the general management of the trauma patient (see Chapter 33). In patients who are intubated, have a massively distended abdomen, or in whom there is a high concern for stomach or duodenal injury, a nasogastric tube should be placed to decompress the abdomen, decrease the likelihood of aspiration, and determine whether blood is present, respectively. Placement of an orogastric tube is preferable in patients with midface or skull base fractures. Foley catheterization, once fairly routine, is reserved for unconscious patients, and those in shock, for whom urine output is an indicator of adequate end-organ perfusion. Thoracotomy and subsequent cross-clamping of the descending aorta have been used to stabilize patients with thoracoabdominal injuries and profound hypovolemic shock, but this is best undertaken as a temporizing rescue maneuver in the operating room when laparotomy identifies critical injuries not amenable to abdominal repair. ED thoracotomy for management of intra-abdominal injuries, even exsanguinating injuries, rarely is indicated, and the decision to undertake thoracotomy rests with the treating trauma surgeon.

Antibiotics, given prophylactically, are effective in decreasing the incidence of intra-abdominal sepsis. Intestinal perforation and soiling can occur with penetrating, and uncommonly with blunt trauma to the abdomen. A single preoperative dose of a broad-spectrum antibiotic or combination of antibiotics that covers both aerobic and anaerobic organisms, such as piperacillin-tazobactam 3.375 g intravenously, is recommended.

Penetrating Abdominal Trauma: Stab Wounds

Selective management of abdominal stab wounds is now well accepted because of the relatively low incidence of intraperitoneal injuries coupled with the success of various diagnostic strategies. This strategy is based on the site of penetration, the clinical status of the patient, and the experience and judgment of the hospital institution and its personnel. Compared to the former practice of mandatory laparotomy, selective management has resulted in a tremendous reduction in unnecessary laparotomies and their associated morbidity, with minimal and acceptable loss in sensitivity for significant intraperitoneal injury. Overall, the nontherapeutic laparotomy rate should be less than 15%.
Anterior Abdomen

In approaching the management of stab wounds to the anterior abdomen, the clinician is faced with three fundamental tasks. The first and most important is to determine whether clinical indications exist for emergent laparotomy. The presence of one or more of these indications, particularly in the context of an unstable patient, sets the course to exigent operation. If none is found, the clinician may address the second issue of whether the peritoneal cavity has been violated. If it can be definitively demonstrated that it has not, no further diagnostic evaluation is required, and the patient can be discharged after appropriate wound care. If the cavity has been violated, or if it cannot be determined whether the cavity has been violated, the third question is pursued: Does an intra-peritoneal injury exist and, if so, is laparotomy required? One general approach to abdominal stab wounds founded on these three queries is summarized in Figure 39.6. This algorithm is largely based on clinical indicators of injury, LWE, CT, and other radiologic modalities. Other strategies rely more heavily on other techniques, such as serial abdominal examinations or laparoscopy.

Step I: Clinical Indications for Emergent Laparotomy. Various clinical determinants can be used to determine the need for emergent laparotomy (Table 39.2) based on the likelihood of associated intra-abdominal injuries requiring surgical repair. These clinical determinants are summarized in the following list by reasons for immediate laparotomy, followed by clinical indications that require additional supportive evidence.

A: Emergent laparotomy immediately indicated

1. Hemodynamic compromise: This is the preeminent indication of the need for laparotomy in the setting of a stab wound and is the most likely reason that a patient will be taken urgently to the operating room without preliminary diagnostic studies.

2. Peritoneal signs: There is considerable debate over the reliability of peritoneal signs, particularly in the early post-injury period. Among physical examination findings, unequivocal peritoneal signs have the highest positive predictive value, whereas an entirely normal examination even in the presence of mild to moderate intoxication has the greatest negative predictive value for therapeutic laparotomy. In general, however, clear peritoneal signs indicate the need for laparotomy.

3. Evisceration: Patients with viscus evisceration sustain up to an 80% incidence of major intraperitoneal injury, and most surgeons will take these patients for exploratory laparotomy. In rare cases, for isolated omental evisceration without viscus evisceration and absence of free intraperitoneal blood on E-FAST examination, the surgeon may ligate, excise, and restore the omentum to the peritoneal cavity. This is done at the bedside in the trauma bay.

4. Left-sided diaphragmatic injury: Although rarely diagnosed acutely, left-sided diaphragmatic injury may be diagnosed through the observation of stomach or bowel in the left chest on bedside chest radiographs, and indicates the need for operative intervention.

B: Laparotomy only considered with additional clinical evidence

5. Gastrointestinal hemorrhage: Again, although rarely diagnosed because nasogastric tubes are rarely used in this clinical scenario, recovery of blood via a nasogastric tube or emesis may reflect a violation of the stomach or duodenum. However, blood without coincident peritoneal violation does not necessarily require surgical exploration.

6. Implements in situ: The conservative and widely held maxim is to remove implements in situ of the torso in the operating room. However, there is little evidence to support this practice and removal of such instruments in the ED under controlled circumstances, and in consultation with a surgeon, is reasonable.

7. Intraperitoneal air: See later.

**Step II: Peritoneal Violation.** If clinical indications for laparotomy are absent, a logical next step is assessing the wound tract itself. The presence of peritoneal violation can be determined by a variety of means. There is great value in establishing that a wound tract is superficial to the peritoneal, retroperitoneal, intrathoracic, and pericardial cavities. In this event, the patient can be discharged from the ED after receiving appropriate wound care. If a study is inconclusive, it should be assumed that one or more of these cavities has been violated and further means of assessment are required. The five methods of assessing whether the peritoneum is intact are as follows:

1. Evisceration: Evisceration of bowel or omentum is clear evidence of peritoneal entry. Although typically mandating laparotomy, exceptions exist (see earlier).

2. Intraperitoneal air: Although a finding of intraperitoneal free air on an upright chest or a lateral decubitus abdominal radiograph may indicate bowel perforation, it may simply establish that the implement has entered the peritoneal cavity and drawn air in with it. Therefore, although intraperitoneal air is a strong indication of peritoneal violation, it does not necessarily imply bowel injury and is therefore not used in isolation to determine the need for emergent laparotomy. Rarely, a false-positive determination of peritoneal entry can be made when the actual source of intraperitoneal free air is the pulmonary tract.

3. LWE: This has been demonstrated to be an effective tool in determining if the peritoneal cavity has been penetrated. Superficial wounds can be repaired if needed and the patient discharged from the ED.

4. Ultrasonography: E-FAST examination demonstrating hemoperitoneum, pneumoperitoneum, or pericardial effusion (see Fig. 39.2) identifies peritoneal penetration or injury. A negative E-FAST does not rule out peritoneal violation. Presence of intraperitoneal blood on ultrasonography precludes the need for LWE.

5. Laparoscopy or thoracoscopy in the operating room: This has compared favorably with LWE in assessing the wound tract but requires a surgeon’s expertise and carries a greater risk of complications. Benefits include the ability to detect organ injury (including diaphragmatic injury) and simultaneously repair some injuries, thus decreasing negative and nontherapeutic laparotomy rates. Its primary use is in evaluating for diaphragmatic violation in left anterior lower chest stab wounds.

**Step III: Injury Requiring Laparotomy.** In this algorithm, patients requiring an operation on clinical grounds have proceeded to laparotomy, and those in whom peritoneal violations have been excluded are discharged home. The patients remaining have presumed or known peritoneal violation. The next consideration is whether injury exists that dictates operative repair, because organ injury is present in only just over 60% of patients with peritoneal violation. In any case, patients who reach this stage of evaluation should be observed for at least 12 to 24 hours.

Initial CT scanning coupled with serial E-FAST, and physical examinations are used to identify significant wounds not initially obvious. Hollow viscus and occult diaphragmatic injuries remain the most frequently missed injuries on CT. Laparoscopy is performed when serial evaluation suggests possible, but not obvious, need for laparotomy.

**Thoracoabdominal Penetration**

Even a single stab wound to the low chest can violate the mediastinum, thoracic cavity, diaphragm, peritoneal cavity, and retroperitoneum. Nearly 20% of left thoracoabdominal stab wounds will be found to have diaphragmatic violation. When all thoracoabdominal wounds are considered, the risk of occult injury is 7%. Ultrasonography can be extremely useful by permitting quick assessment for hemopericardium and hemoperitoneum in the marginally stable patient if thoracotomy or laparotomy is not already clinically indicated. LWE of slash-type wounds may obviate the need for further evaluation, but the depth of investigation cannot be taken beyond the anterior rib margin to maximize safety and accuracy.

**Diagnosis of diaphragmatic injury is particularly problematic.** CT has sensitivity and specificity in the low 90% range for detecting diaphragmatic injury. However, equivocal scans should be followed up with more definitive management, such as laparoscopy or thoracoscopy.

**Flank and Back**

The incidence of retroperitoneal injuries after stab wounds to the flank and back is greater than with injury to the anterior wall. However, risk of intraperitoneal organ injury also is significant, ranging up to 40%. LWE is less accurate than in anterior wounds because the paraspinal muscles are quite thick, so the procedure is only useful if the wound is obviously superficial (such as, a slash wound). CT with intravenous contrast is the method of choice for evaluating wounds not identified to be clearly superficial. A negative CT scan, followed by serial examination over a period of 24 hours, can effectively exclude serious injury management of these patients.

**Penetrating Abdominal Trauma: Gunshot Wounds**

Unlike stab wounds, almost all gunshot wounds penetrate the peritoneal cavity and typically produce multiple organ injuries and a high incidence of hollow visceral injury. Accordingly, the risk of mortality is significantly greater and increases with the velocity of the missile. Missiles striking the low chest commonly penetrate both intrathoracic and abdominal structures, including the diaphragm.

Abdominal gunshot wounds enter the peritoneal cavity in approximately 80% of cases, and in more than 90% of those involving penetration, there is intraperitoneal damage. Although selective management is widely accepted for stab wounds, its application in the management of gunshot wounds is extremely limited, and therefore mandatory laparotomy generally is the rule, rather than the exception. First and foremost, are there clinical grounds for immediate operation? Second, if none exists, has peritoneal violation occurred? If the answer to either of these questions is yes, the patient is taken emergently to laparotomy with very few exceptions. If no peritoneal violation occurred, or it is unclear, admission for serial examinations is indicated (Fig. 39.7).

**Step I: Clinical Indications for Laparotomy**

If the patient is hemodynamically unstable, or peritoneal signs are present, the patient is taken immediately for operative intervention.

**Step II: Peritoneal Violation**

If patient does not meet indications for immediate laparotomy, assessments are made to determine if peritoneal violation is

Fig. 39.7. Abdominal gunshot wound algorithm. LAP, Laparotomy.*Can be assessed by missile path, plain films, local wound exploration (LWE), ultrasonography, and laparoscopy. †Most centers proceed to laparotomy if peritoneal entry is suspected. ‡Patients with documented superficial and low-velocity injuries can be discharged; unknown-depth or high-velocity injuries require further tests or observation. §Computed tomography (CT), diagnostic peritoneal lavage (DPL), laparoscopy (LPY), or serial physical examinations (SPEs) can be used in singular or complementary fashion, depending on the clinical scenario. ‡Expectant management of injuries caused by gunshot wounds is rarely attempted.

present. Six methods are used to determine whether the missile has entered or traversed the peritoneal cavity:

1. Missile path: If the missile clearly just grazed the superficial tissue of the abdominal wall, it can be identified as non-penetrating.

2. Plain radiographs: An anteroposterior and lateral projection of the abdomen can assist in placing the missile in the peritoneal cavity, but such estimations are imprecise and are largely unhelpful in patients with through-and-through or multiple gunshot wounds.

3. LWE: This is used highly selectively in apparent grazing injuries or occasional injuries from handguns that appear to go through and through the lateral abdominal wall, well outside the confines of the peritoneum. If LWE confirms the path as superficial, violation has not occurred.

4. Ultrasonography: Presence of fluid on E-FAST indicates penetration, regardless of the impression one has derived from the apparent path of the missile.

5. Laparoscopy: Laparoscopy is used when peritoneal violation is known or suspected, but physical examination and E-FAST suggest that intraperitoneal injury is minimal or absent.

6. CT: CT has been helpful when trajectory is indeterminate and has extremely high sensitivity and specificity for identifying intra-abdominal injury. It can also identify the wound track, whether fragmentation has occurred, and indicate vascular structures at risk for injury, although this is more useful in neck wounds.

Thoracoabdominal

Half of the patients with gunshot wounds to the low chest have intraperitoneal injuries. Clinical indications for emergent or urgent laparotomy are as for abdominal gunshot wounds. CT scanning is highly accurate for identification of both chest and abdominal injury and should be obtained before the patient goes to the operating room, unless the patient’s instability will not allow this.

Flank and Back

CT scan is highly accurate for identification of retroperitoneal injury and is the diagnostic test of choice in a stable patient. Most patients are then taken to the operating room. In some cases of low velocity gunshot wound to the flank, laparoscopy or observation alone can be used if the CT scan shows no evidence of injury and the bullet track does not traverse any anatomically important structures.

Shotgun Wounds

Type I injuries can be effectively managed by reserving laparotomy for patients with clear peritoneal signs or progressive abdominal tenderness. Certain authors advocate an expectant approach to type II injuries, stating that small punctures of the bowel cause no wound eversion and no peritoneal leakage and will spontaneously close. A more prudent approach is to perform laparotomy in cases of these penetrating wounds, especially if there are signs of peritonitis. Reconstruction of abdominal wall defects may be required. Type III injuries are commonly associated with multiple organ injuries, shock, and pronounced tissue destruction, requiring hemostasis and extensive débridement.

Blunt Abdominal Trauma

In cases of blunt trauma, it is the exception when a patient undergoes laparotomy based on clinical grounds alone. Far more typically, one or a complementary battery of diagnostic tests are performed. The choice of these tests is influenced by the patient’s hemodynamic status, the clinical scenario, and the institution’s resources and preferences (Fig. 39.8).

The decision to perform immediate laparotomy after injury from a blunt mechanism is rarely determined solely by clinical parameters. Immediate transport to the operating room is reserved to patients with (Table 39.3):

1. Refractory hypotension in a patient with positive E-FAST examination for hemoperitoneum and absence of an unstable pelvic fracture
2. Obvious peritonitis with positive E-FAST examination
3. Evidence on E-FAST of intra-abdominal injury in the context of other life-threatening injuries, such as uncontrollable chest hemorrhage, which require transfer to the operating room

In patients who are hemodynamically stable, CT scanning is the diagnostic modality of choice, as outlined earlier.

Operative Versus Nonoperative Management

Patients with certain intraperitoneal injuries, even moderate- to high-grade liver or spleen trauma, often can be managed without laparotomy. The patient with normal sensorium and minor to intermediate severity of mechanism is a superior candidate for expectant management. It is critical that an institution appraise its ability to manage such patients, which includes having experienced nursing staff, trauma surgeons, adequate blood resources, and radiologists and the ability for the patient to undergo laparotomy urgently if the need arises at any time of day or night.

Several pitfalls in the expectant approach are noteworthy. First, hollow viscera injury, when present, requires operative management. The ability of the CT scan to detect injury to these structures is discussed earlier. The patient with multisystem injury

such cases, the lag time from injury to operation may increase morbidity and mortality.

**Pelvic Fracture**

In the setting of pelvic fracture, the clinical triage determinant is the presence or absence of hemoperitoneum (Fig. 39.9). Although the sensitivity of E-FAST in patients with pelvic fractures may be decreased, it still serves as a tool to triage the patient to the next intervention. In an unstable patient, if the E-FAST is negative, then the patient should proceed to therapeutic angiography with the presumed diagnosis of a life-threatening retroperitoneal bleed. In all patients, early mechanical pelvic stabilization is advised (see Chapter 48), and CT scan followed by pelvic angiography and embolization are undertaken as early as possible in the context of the multiple injuries.

**Multiple System Injury**

It is not unusual to confront intraperitoneal hemorrhage in a patient with apparent closed head injury or suspected blunt aortic disruption or both. Repair of the abdomen is said to take precedence over that of the head and chest. However, these situations are highly complex, and decision-making is influenced by numerous and dynamic variables, and approaches to two of these situations are summarized in Figures 39.10 and 39.11. The key tenet is that a patient with known hemoperitoneum whose vital signs cannot be stabilized should undergo laparotomy to avoid exsanguination.

**Bedside Procedures**

**Diagnostic Peritoneal Lavage**

Once the mainstay of evaluation of the abdominal trauma patient to determine the presence of injury and the need for laparotomy, diagnostic peritoneal lavage now is largely of historic interest only. Its remaining role in trauma is limited to centers where ultrasound equipment is not available or the clinician is not trained to perform ultrasound.

**Local Wound Exploration**

LWE is used to determine whether an anterior stab wound has penetrated into the peritoneal cavity in a non-obese patient. The
wound is infiltrated with a local anesthetic containing epinephrine then carefully visualized through each successive layer of tissue. Blind probing with digits, instruments, or cotton-tipped swabs is inaccurate, unless the peritoneal cavity is obviously freely entered. If LWE indicates that the peritoneum is not violated, the E-FAST is negative, and the patient is otherwise uninjured, the injury can be treated as a local abdominal wall injury, and the patient is treated and discharged. Indication of entry into the peritoneal cavity or inability to locate the end of the wound tract are indications for ongoing observation or abdominal CT scan (see Management).

Wound explorations in patients with multiple entrances are not economical and require extensive effort, and it may be wiser to assume peritoneal penetration. Deep exploration over the thoracic cage is precluded by attendant complications to neurovascular structures and pleura. However, careful inspection of superficial chest wounds (eg, slash wound) is safe and can provide valuable data.

**Therapeutic Angioembolization**

Therapeutic angiography, a time-consuming procedure, is usually reserved for the unstable patient with blunt trauma and pelvic fracture in whom it can be used to embolize bleeding vessels (Fig. 39.12). Laparotomy and angioembolization for pelvic fractures with hemoperitoneum have shown no significant difference in regards to in-hospital mortality regardless of hemodynamic status. It can also be a means of staunching solid visceral hemorrhage from blunt trauma, notably of the spleen. Nonoperative management has become standard in management of splenic injuries but is associated with increasing failure rates with increasing grades of injury, up to 44% with the highest-grade injuries. Successful nonoperative management increases significantly with the use of angioembolization, although higher-grade injuries are still more likely to fail nonoperative management than
as outlined earlier, require operative intervention or prolonged observation on an experienced service. Similarly, consultation with a radiologist may help to prioritize studies, avoid unnecessary studies, or obtain the vital information with the minimum exposure of the patient to ionizing radiation or contrast material.

Transfer

Patients with significant abdominal trauma whether blunt or penetrating should be transferred to a level I, II, or III trauma center as soon as possible after the threatening injury is identified, and without delay for time-consuming imaging studies that will not alter the need for transfer. Trauma patients in non-trauma hospitals with significant transfer times may require a stabilizing damage control laparotomy by a general surgeon before being transferred to a trauma center for definitive care.

Fig. 39.11. Combined wide mediastinum and blunt abdominal trauma algorithm. Fig. 39.12. A, Angiography of splenic laceration. Note the blush representing active hemorrhage (arrow). B, Angioembolization of renal laceration. Note coil in the splenic artery (white arrow) and blush representing active hemorrhage stemming from two branches (black arrows). (A, From Mauro MA: Image guided interventions, Philadelphia, 2008, Elsevier, p 835.)
The accuracy of physical examination is limited in cases of abdominal trauma. It is rendered less reliable by distracting injury, altered sensorium (e.g., head trauma, alcohol or drug intoxication, developmental delay, psychiatric illness), and spinal cord injury.

- Stab and gunshot wounds frequently violate the lung parenchyma, diaphragm, mediastinum, intraperitoneal cavity, and retroperitoneum in some combination.
- Physical examination with E-FAST, followed by CT scan when indicated, provides accurate diagnosis for the majority of blunt and penetrating abdominal trauma patients.
- Emergent laparotomy is indicated for patients sustaining a stab wound in the setting of hemodynamic compromise, peritoneal signs, evisceration, or left-sided diaphragmatic injury. Patients not meeting these criteria undergo a combination of LWE, CT scan, serial examination and E-FAST, depending on the location of the wound.
- Emergent laparotomy is indicated for patients sustaining a gunshot wound in the setting of hemodynamic compromise, peritoneal signs, or peritoneal violation. Patients not meeting these criteria undergo a combination of LWE, CT scan, serial examination and E-FAST, depending on the location of the wound.
- The critical determinant in hemodynamically unstable patients with pelvic fracture is the existence of active intraperitoneal hemorrhage. Discovery of this by E-FAST, CT scan, or peritoneal aspiration is an indication for laparotomy, whereas its absence prompts diagnostic and potentially therapeutic angiography.

The references for this chapter can be found online by accessing the accompanying Expert Consult website.
1. The focused assessment with sonography in trauma (FAST) scan of a patient with blunt abdominal trauma shows a hypoechoic stripe in the pouch of Douglas. Which of the following is correct? 

A. In the presence of hemodynamic instability, this indicates a need for laparotomy. 

B. The patient needs to go for emergent laparotomy. 

C. The patient requires repeat abdominal examinations and FAST examinations in the emergency department (ED). 

D. There is at least 50 mL free fluid in the abdomen. 

E. This indicates a ruptured bladder. 

Answer: A. The pouch of Douglas is one of the areas of ultrasound inspection for a FAST examination. If free fluid is present and the patient is hemodynamically unstable, the patient should forego computed tomography (CT) scanning for the operating room. FAST examinations are effective in detecting as little as 100 mL of free fluid in the abdominal cavity. 

2. An 18-year-old man presents after a moderate-velocity front-end vehicle collision. He has a blood pressure of 110/70 mm Hg, heart rate of 120 beats per minute, respiratory rate of 17 breaths per minute, and a Glasgow Coma Score (GCS) of 13. On physical examination, he has a tender abdomen and an unstable pelvis. A FAST examination is positive for free fluid in the abdomen. What should be the next step in this patient’s management? 

A. Admission to the trauma service for observation 

B. Diagnostic peritoneal lavage (DPL) followed by laparotomy if 5 mL blood is aspirated 

C. DPL followed by laparotomy if 10 mL of grossly bloody aspirate is obtained 

D. Emergency laparotomy 

E. ED observation for 12 hours with repeat FAST examinations 

Answer: C. Although the sensitivity of FAST examinations for identifying intra-abdominal injuries requiring surgical intervention is not high, it still serves as a tool to triage patients to the next intervention. In an unstable patient, a positive FAST ultrasound scan is followed by a suprapubic peritoneal aspirate. If this reveals 10 mL or more of blood, then the patient should expeditiously move to laparotomy. 

3. Which of the following is not an advantage of CT scanning over diagnostic peritoneal lavage (DPL) in assessing patients with blunt abdominal trauma? 

A. Identification of hemorrhage 

B. Evaluation of genitourinary injury 

C. Evaluation of retroperitoneum 

D. Evaluation of unstable trauma patients 

E. Quantification of hemorrhage 

Answer: D. In most situations, CT scanning has supplanted DPL because of its higher predictive ability for operative lesions and the fact that it is noninvasive. CT scanning can define the injured organ and the extent of the injury. It is most accurate for solid visceral lesions and accurately discerns the presence, source, and approximate quantity of intraperitoneal hemorrhage. It can demonstrate active bleeding from the liver or spleen, and it can be used to determine whether therapeutic angiographic embolization is indicated. CT scanning also evaluates the retroperitoneum. In cases of blunt trauma, DPL’s primary remaining use is the triage of the patient who is hemodynamically unstable and has multiple injuries with an equivocal FAST examination. 

4. Which of the following statements regarding radiation exposure from CT scans in the setting of blunt abdominal trauma is false? 

A. A single CT scan may increase the lifetime risk of cancer. 

B. CT scans are never indicated in pregnancy, given the risk of radiation to the fetus. 

C. Institutions should follow as low as reasonably achievable (ALARA) principles to mitigate radiation exposure. 

D. Medical radiation may be responsible for 0.4 to 1% of all cancers in the United States. 

E. Patients transferred to another facility should have attempts made to convey the images to the receiving facility as long as it does not negatively impact the patient’s care. 

REFERENCE

PART II  
SECTION O  

418.e2

Answer: B. Although there is a risk to the fetus with radiation, there may be situations where the risk of missed injury or exploratory laparotomy outweighs the risk of radiation to both mother and fetus. Patients being transferred to another facility should have attempts made to provide CT scans either in hard copy or digitally, to minimize repeat radiation exposure to the patient. Current estimates suggest at least 0.4% of all cancers in the United States are secondary to medical radiation, and a single CT scan may increase the lifetime risk of cancer. Facilities can minimize this risk by adopting ALARA principles.

39.5. A 27-year-old male presents 4 hours after an isolated stab wound to the anterior abdomen. His vital signs are heart rate 84 beats per minute and blood pressure 115/64, and the lactate level is 0.9 mg/dL. His focused assessment with sonography in trauma (FAST) examination is negative for free fluid. He denies alcohol and drug use and appears clinically sober. Which of the following statements regarding this patient’s subsequent management is true?

A. A diagnostic peritoneal lavage (DPL) with 250,000 red blood cells per mm³ indicates the need for admission and serial abdominal examinations.
B. A local wound exploration (LWE) that fails to demonstrate peritoneal violation means that the patient can be discharged from the emergency department (ED).
C. A negative computed tomography (CT) scan rules out the need for further evaluation.
D. The negative FAST examination rules out intra-abdominal injury requiring operative intervention.
E. The patient meets criteria for emergent laparotomy.

Answer: B. Simple anterior abdominal stab wounds that do not violate the peritoneum can be discharged from the ED after appropriate wound care (see Fig. 39-6). Not all anterior stab wounds meet indication for laparotomy, even in the presence of peritoneal penetration. A DPL of greater than 100,000 red blood cells (RBCs)/mm³ is an indication for laparotomy in abdominal stab wounds. A negative FAST examination does not rule out significant intra-abdominal injury or even small-volume hemo-peritoneum in either penetrating or blunt abdominal trauma. CT scans poorly visualize both the small bowel and diaphragm and cannot be used in isolation to rule out injury in penetrating abdominal trauma.

39.6. A 67-year-old female who is taking warfarin (Coumadin) for atrial fibrillation presents after a high-mechanism motor vehicle collision. Her heart rate is 142 beats per minute and blood pressure is 84/40 after 1 L of normal saline. Her Glasgow Coma Score (GCS) is 6, and her left pupil is 6 mm versus 3 mm on the right. Her physical examination is notable for a seat belt sign on the abdomen. Which of the following is not an acceptable approach to her initial assessment and treatment?

A. Perform a focused assessment with sonography in trauma (FAST) examination to evaluate for the presence of intra-abdominal fluid.
B. Perform chest and pelvic radiographs in the resuscitation bay.
C. Perform empirical craniotomy concurrently with laparotomy in the operating room after a positive diagnostic peritoneal aspiration.
D. Perform endotracheal intubation and begin mild hyperventilation.
E. Proceed to radiology for an emergent abdominal CT scan.

Answer: E. The patient is hemodynamically unstable, with suspected intra-abdominal injuries in conjunction with signs of herniation. CT scanning of the abdomen would be inappropriate in this patient. Several concurrent management options to stabilize the patient and determine the source of her hypotension are desirable (see Fig. 39.10). Endotracheal intubation allows airway control and possible hyperventilation to delay impending herniation. Chest and pelvic radiographs rule out other sources of ongoing hemorrhage and may support emergent laparotomy. A FAST examination can confirm the presence of intra-abdominal free fluid, which in the setting of hemodynamic instability is an indication for laparotomy. Finally, after confirmation of intra-abdominal blood by either digital pulse analyzer (DPA) or FAST, proceeding to the operating room, with or without emergent CT scanning of the head, are management options. If the head CT is foregone because of instability, empirical craniotomy is an acceptable management option.

39.7. Which of the following statements regarding splenic injuries in blunt abdominal trauma is false?

A. A CT scan with a grade IV splenic laceration indicates the need for laparotomy.
B. Angiographic embolization may preserve some of the immune function of the spleen, even in the setting of a grade V laceration.
C. Bedside focused assessment with sonography in trauma (FAST), although sensitive for intra-abdominal fluid, is a relatively poor test for the evaluation of solid organ injury.
D. CT scanning followed by serial abdominal examinations and hematocrits is a reasonable management option at experienced centers.
E. Mononucleosis increases the risk of splenic laceration from seemingly minor blunt abdominal trauma.

Answer: A. High-grade splenic lacerations, although having a higher rate of failed nonoperative or angiographic embolization management, do not represent a definitive indication for laparotomy. Trauma can be so minor that the patient may have little recollection of the remote trauma responsible. Serial abdominal examinations, laboratory tests, and/or repeat FAST examinations are reasonable management options at experienced centers. Limited studies have suggested that angiographic embolization does preserve some of the immune function of the spleen compared with splenectomy. The FAST examination does not visualize solid organ injury effectively enough to eliminate the need for further evaluation with CT scanning in this case, especially because laparotomy is not necessarily indicated.
Ten percent of trauma cases in the United States involve the genitourinary tract, and most of these injuries are not life-threatening. In fact, due to the anatomic protection of the kidneys, ureters, and bladder, as well as the mobile nature of the male external genitalia, isolated urologic injuries are uncommon in patients involved in major trauma. However, genitourinary trauma can cause significant, long-term morbidity, including renal insufficiency, chronic hypertension, incontinence, and sexual dysfunction. Additionally, traumatic renal injuries can be overlooked, due to the location of the kidneys and subtle presentation, with serious consequences for the patient.

Almost three-quarters of all blunt injuries are caused by motor vehicle collisions, but seat belts and air bags have been shown to result in substantially fewer high-grade renal injuries and, as a result, fewer nephrectomies. Seat belts and air bags can also cause injuries to the kidneys, although the benefits of these protective devices have been shown to outweigh the risks. Forty percent of patients with renal trauma have a coexistent abdominal injury.

Blunt trauma is responsible for nearly all cases of pediatric renal trauma. Kidney injuries are more common than injuries to the spleen, liver, pancreas, and bowel in this population. However, due to more conservative approaches in management, pediatric renal trauma now only rarely leads to nephrectomy.

Due to the long, tubular nature of the ureter and its location in the retroperitoneum where it is well protected by the vertebral and soft tissues, blunt traumatic injuries of the ureter are rare and virtually never occur in isolation. Most noniatrogenic ureteral injuries are due to penetrating mechanisms; the ureter is involved in up to 5% of penetrating injuries to the abdomen. After the kidney, the bladder is the most commonly injured genitourinary organ with blunt trauma; this happens most frequently from motor vehicle collisions, which are responsible for approximately 90% of cases. Bladder injury most often occurs in the context of pelvic fractures or other intra-abdominal injuries, and the mortality rate in patients with blunt bladder trauma is therefore as high as 22%. The bladder also is subject to penetrating injury through the abdomen, rectum, or buttocks. Up to 80% of patients with penetrating bladder injuries also suffer bowel injuries.

Blunt trauma mechanisms, the majority of which are motor vehicle collisions, are responsible for approximately 90% of urethral injuries. Males are five times more likely than women to suffer urethral injuries due to the increased overall incidence of trauma in males, and the longer length and reduced mobility of the male urethra. Similar to bladder injuries, significant blunt pelvic trauma is typically required to cause injuries to the urethra. As a result, concomitant injuries are often observed, with significant pelvic fractures or straddle-type injuries involved in the majority of cases. Penetrating injuries to the urethra are rare and are suspected on the basis of the nature and trajectory of the penetrating object. Urethral trauma also can occur from misadventure during self-instrumentation, which is most often related to sexual activity. Urethral injury can cause significant morbidity, due to stricture formation, incontinence, impotence, and infertility, even if urethral injuries are appropriately diagnosed and treated.

The external genitalia, particularly the scrotal contents, are subjected to direct injury, which happens most often in sports-related trauma. Minor external trauma may occur with consumer products (including zippers, sporting items, and furniture), and the large majority of these injuries are self-limited. Severe injuries, including penile fractures and testicular rupture, are rare but generally require hospital admission. These injuries also can lead to long-term reproductive, physiologic, and psychological consequences.

Although the overall rates are low in females, up to 8% of reported childhood trauma in girls involves the external genitalia. Sexual abuse is much more commonly the cause than accidental trauma in this age group (see Chapter 177).

The genitourinary tract is divided into the upper tract (kidneys and ureters, including the renal pedicle), lower tract (bladder and urethra), and external genitalia (penis, scrotum, testicles, and vulva).

The kidneys are retroperitoneal organs that are encapsulated by fibrous tissue known as Gerota’s fascia. They lie against the psoas muscles, are surrounded by the ribs and spinal column, and are well-cushioned by perinephric fat, leaving them fairly well-protected (Fig. 40.1). This explains why isolated renal injury is rare in trauma, because it often requires a significant mechanism to cause injury. However, the lower poles of the kidney do project inferior to the twelfth rib bilaterally, which makes them susceptible to trauma. Due to their proportionately larger kidneys with less perirenal fat, weaker abdominal muscles, and a less rigid chest wall, children are at higher risk for renal injury.

The renal pedicle—which includes the renal artery, renal vein, and the ureter—inserts into the kidney along the medial border, at the hilum. A longitudinal cross-section of the kidney reveals the outer renal cortex with inner medulla that compose the renal parenchyma (Fig. 40.2). These create and drain urine into the calyces, which flow into the renal pelvis, which then drains into the ureter.

The bladder is a muscular organ that lies in the abdomen at birth but descends into the pelvis at around 6 years old and is, thus, considered extraperitoneal. It is heavily protected by the bony pelvis, especially when it is not distended. However, when distended, the dome of the bladder rises into the abdomen (as high as the umbilicus), making it more prone to both blunt and penetrating trauma. Posteriorly, the bladder connects to the ureters on the superior aspect, and in males, it is adjacent to the seminal vesicle and vas deferens on the inferior side. Loose connective tissue surrounds the bladder laterally.

The male urethra is approximately 22 cm in length when measured from the bladder to the urethral meatus (Fig. 40.3). The
The penis is composed of two paired corpora cavernosa along the dorsal aspect and a corpus spongiosum along the ventral surface (Fig. 40.5). The corpora cavernosa are filled with venous sinusoids that surround a central artery and engorge with blood during an erection, whereas the corpus spongiosum surrounds the urethra and forms the glans penis on its distal aspect. Each of the three is surrounded by a separate fascial sheath, which also is referred to as the tunica albuginea. Buck’s fascia, the deep fascia of the penis, immediately surrounds the three structures, and multiple other superficial fascial layers further surround Buck’s fascia. The superficial and deep dorsal veins provide most of the venous drainage from the penis.

Pathophysiology

Because it is fixed in space only by the renal pelvis and pedicle, the kidney is prone to acceleration and deceleration injuries from blunt trauma. The American Association for the Surgery of Trauma (AAST) guidelines for grading blunt renal trauma are essentially unchanged since their creation in 1989, with grades III, IV, and V defined as “high grade” renal trauma (Table 40.1 and Fig. 40.6). Lacerations and contusions typically occur from direct trauma, whereas renal artery avulsions can occur from deceleration mechanisms. Renal artery thrombosis can occur when the renal artery is compressed between the anterior abdominal wall and vertebral bodies. Penetrating injuries, typically due to gunshot and stab wounds, can cause similar patterns of injury as blunt injuries.

Blunt injuries can cause trauma to the ureter either directly from compression against fractured bony structures (such as, transverse processes of lumbar vertebrae) or by deceleration mechanisms, which can cause a disruption at the ureteropelvic and ureterovesical junctions. Due to their hyperextensible vertebral columns, children are more prone to deceleration mechanisms. Penetrating injuries are almost exclusively unilateral, and
CHAPTER 40  Genitourinary System

Bladder injuries range from mural contusions (representing 50% of injuries) to bladder ruptures, which are defined as lacerations through the entire wall of the bladder. Ruptures are further classified into intraperitoneal bladder ruptures (IBRs) and extraperitoneal bladder ruptures (EBRs). Intraperitoneal injuries resulting from blunt trauma are typically caused by rupture of a distended bladder at its weakest point, which is the dome where it abuts the peritoneum. As a result, urine drains into the peritoneal cavity. EBRs, which account for the majority of bladder ruptures, occur as the result of direct compression, shear forces at the bladder base, or lacerations from bony spicules from pelvic fractures. These ruptures result in urine draining into the pelvic cavity. Approximately 10% of bladder injuries are both intraperitoneal and extraperitoneal in nature.

With blunt trauma to the pelvis, shearing forces transmitted through the urogenital diaphragm create tension along the urethra, most often between the anterior and posterior segments at the bulbomembranous junction. These forces occur commonly in unstable pelvic fractures, bilateral ischiopubic rami fractures, and symphysis pubis diastasis injuries. In fact, the combination of anterior pelvic ring fracture with sacroiliac joint disruptions posteriorly present with a concomitant posterior urethral injury.

Fig. 40.3. Anatomy of male genitalia.

Fig. 40.4. Scrotal anatomy.

Fig. 40.5. Cross-sectional view of the penis.
in approximately 25% of cases. Injuries can range from stretching, to partial lacerations, to complete disruptions of the urethra; the latter of which accounts for approximately 50% to 65% of urethral injuries. The majority of these injuries involve the posterior urethra, and the most severe injuries are complex posterior injuries involving the bladder neck or rectum.

Anterior urethral injuries, which are four times less common than posterior injuries, are often caused by blunt straddle-type injuries, which result in crushing of the bulbar urethra against the inferior aspect of the pubic bone (Fig. 40.7). These injuries occur more commonly in children and can be easily missed, potentially resulting in future strictures. Gunshot wounds and other penetrating injuries involve the anterior urethra more commonly than the posterior urethra.

Besides testicular rupture, which is caused by disruption of the testicular tunica albuginea, blunt trauma can also lead to scrotal hematomas, testicular contusions, testicular fractures, testicular dislocation, or even traumatic testicular torsion and traumatic epididymitis. In fact, significant injuries occur in up to 45% of all patients presenting with blunt trauma to the scrotum. Testicular hematomas form within the testicle and may be associated with testicular rupture, whereas testicular fractures are defined as linear avascular areas within the testicular parenchyma without rupture of the tunica albuginea. Testicular dislocation occurs when blunt trauma forces the extra-scrotal migration of one or both testicles, although bilateral dislocations are rare. They migrate along the course of the spermatic cord and typically are found in the superficial inguinal area, but they can even be found in the suprapubic region. Penetrating injuries often violate the tunica albuginea.

Penile fractures, due to tears of the tunica albuginea, account for the majority of blunt penile injuries that present to the emergency department (ED). Blunt trauma can also lead to rupture of the dorsal veins or artery, resulting in local ecchymosis that can be easily mistaken for a penile fracture, and is therefore termed a *false penile fracture*. Penetrating injuries to the penis involves the urethra in up to 29% of cases and can also result in penile amputation, which is more common in patients with a psychiatric history.

Nonsexual genital injuries in females are most often due to straddle injuries in young girls, but other blunt and penetrating injuries do occur and are often more severe. The labia are most frequently involved, as well as the perineum. Penetrating injuries can involve the rectum as well as urethra, and these deeper injuries

*Fig. 40.6.* Schematic of the American Association for the Surgery of Trauma (AAST) grading scale for renal trauma. (From Myers JB, Brant WO, Broghammer JA: High-grade renal injuries: radiographic findings correlated with intervention for renal hemorrhage. Urol Clin North Am 40:335–341, 2013.)
can easily be missed in young girls if a thorough examination is not performed.12

The diagnostic and management approach to each organ varies, necessitating a basic understanding of the anatomy and traumatic pathophysiology of each individual organ. The majority of cases require early urologic consultation. The clinical features, diagnostic approach, and management guidelines for the specific organs are discussed in the following sections.

**RENNAL TRAUMA**

**Clinical Features**

The history for patients with potential renal trauma includes the mechanism of injury for blunt trauma and the type of implement or weapon for penetrating injury. Significant genitourinary injury is rare in the absence of high energy blunt trauma, unless the trauma is localized to a full bladder or the external genitalia. Gross hematuria warrants careful evaluation for significant genitourinary injury, although the degree of hematuria does not necessarily correlate with the degree or grade of injury, and significant genitourinary trauma can occur without hematuria.5 Renal injury requiring intervention is rare in the absence of gross hematuria or shock. Examination of the patient with multisystem trauma may reveal shock, flank tenderness, mass, or ecchymosis; loss of flank contour; obviously fractured ribs; abdominal tenderness; or an abdominal mass.25

**Differential Diagnosis**

Blunt or penetrating trauma can result in a range of injuries to the kidney and the vascular supply to the kidney, as shown in Table 40.1. Injuries to the renal parenchyma can cause contusions or lacerations within the kidney or hematomas surrounding the kidney. Vascular injuries can involve the renal artery or vein and vary in significance. Minor injuries to the vascular supply can lead to a contained hematoma, but hilar avulsion can result in complete devascularization of the kidney.1

**Diagnostic Testing**

Although significant renal injury can occur without causing hematuria, 95% of all patients with renal trauma have some hematuria on urinalysis, which is defined as more than five red blood cells per high power field. Patients with multisystem trauma, especially with evidence of blood loss, require a complete blood count and type and screen. Creatinine drawn within an hour of injury reflects renal function prior to the injury and, thus, serves as a baseline for future testing.25

Microscopic hematuria in a blunt trauma patient without shock is not an indication for renal imaging, even if there is evidence of local trauma (eg, costovertebral angle tenderness or localized ecchymosis). Although renal injury may uncommonly be identified on imaging for these patients, the injuries are mild and do not require intervention. Hemodynamic instability with evidence of intraperitoneal injury on abdominal examination, presence of pelvic fracture, a penetrating trauma mechanism, or presence of lower rib fractures, with or without hematuria, are indications for further investigation. Additionally, imaging is advisable for patients with gross hematuria, targeted to the entire urinary tract or localized to the lower tract (bladder and urethra), depending on the mechanism and location of the trauma.1

Computed tomography (CT) with intravenous (IV) contrast is the best modality to evaluate for renal injury with nearly 100% sensitivity and specificity. CT can evaluate for renal lacerations, hematomas, extravasation of contrast, devascularized renal segments, and urinary extravasation and thereby grade the severity of renal trauma (Fig. 40.8).26 If there are concerns about collecting system injury (eg, ureteropelvic junction disruption, ureteral injury), delayed images should be performed 10 minutes after administration of contrast (Fig. 40.9).

Ultrasound can demonstrate renal injuries but has lower sensitivity and specificity than CT, and the quality of the study is operator dependent. It is also difficult to determine the depth and extent of renal lacerations, and it is often unclear if fluid seen surrounding the kidney on ultrasound represents urine or blood. However, unlike CT, ultrasound can be performed at the bedside if the patient is unstable. Management of the multisystem trauma patient and the patient with abdominal trauma is discussed in Chapters 33 and 39.

**Management**

Multisystem trauma is managed in collaboration with a general or trauma surgeon, and consultation with a urological surgeon often is indicated when there is injury to the urinary tract.

J Trauma Acute Care Surg 74:558–562, 2013.)
Chapter 40

Genitourinary System

Often explored operatively. Approximately one-third of these patients will require a nephrectomy.29 Consideration has recently been given to further dividing grade IV injuries into IVa and IVb. The distinction is made because patients with grade IV injuries that have CT findings that reveal contrast extravasation, medial or complex lacerations, or hematomas larger than 3.5 cm require surgery more often than patients who do not.30 In fact, patients with two or three of these criteria are 25 times more likely to require an intervention than those with zero or one of these findings.31

Patients with renal artery thrombosis are typically more stable and asymptomatic. Hypertension is often seen with thrombosis of the main renal artery but is rare with segmental artery thrombosis.17 These injuries can result in devascularization of segments of the affected kidney but are also treated conservatively if possible.32

Complications of renal trauma include infection, urinary leak with resultant urinoma, loss of renal function, and hypertension. The most common complication is urinary tract infection.33 In general, antibiotics should be considered for all patients with renal trauma to potentially avoid future urinary tract infections and perinephric abscess formation.29 Grade III, IV, and V injuries are associated with a decrease in renal function of 15%, 30%, and 65%, respectively, after trauma.34

Figure 40.10 represents an algorithm for the management of blunt trauma to the kidneys. After renal trauma is identified on imaging, hemodynamic instability determines the next step. If the patient is unstable despite fluid resuscitation, they should undergo surgical exploration. Patients found to have minor renal injuries (grade I to III) can be managed conservatively with observation and fluid resuscitation. Surgical practice has shifted away from early exploration due to the high number of nephrectomies performed with early exploration.35

Therapeutic options for blunt renal trauma include nephrectomy, ureteric stenting, percutaneous drainage, and arterial embolization.26 Recent changes in management have focused on nonoperative therapy, leading to increased renal salvage. Surgical practice has shifted away from early exploration due to the high number of nephrectomies performed with early exploration. Thirty percent of patients with minor renal trauma undergoing exploration have nephrectomies, but if exploration is performed within 24 hours of arrival, over half undergo nephrectomy. Percutaneous transarterial embolization is being used with increased frequency even for high grade injuries to avoid nephrectomy.27 This shift has been even more pronounced in the pediatric population, where the renal salvage rate now approaches 99%, and patients are treated with stent and nephrostomy if needed.31 In contrast to blunt trauma, penetrating injuries to the kidney are often explored operatively. Approximately one-third of these patients will require a nephrectomy.29

Consideration has recently been given to further dividing grade IV injuries into IVa and IVb. The distinction is made because patients with grade IV injuries that have CT findings that reveal contrast extravasation, medial or complex lacerations, or hematomas larger than 3.5 cm require surgery more often than patients who do not.30 In fact, patients with two or three of these criteria are 25 times more likely to require an intervention than those with zero or one of these findings.31

Patients with renal artery thrombosis are typically more stable and asymptomatic. Hypertension is often seen with thrombosis of the main renal artery but is rare with segmental artery thrombosis.17 These injuries can result in devascularization of segments of the affected kidney but are also treated conservatively if possible.32

Complications of renal trauma include infection, urinary leak with resultant urinoma, loss of renal function, and hypertension. The most common complication is urinary tract infection.33 In general, antibiotics should be considered for all patients with renal trauma to potentially avoid future urinary tract infections and perinephric abscess formation.29 Grade III, IV, and V injuries are associated with a decrease in renal function of 15%, 30%, and 65%, respectively, after trauma.34

** Fever, progressive leukocytosis, hypertension, marked change in symptoms or physical exam

URETERAL TRAUMA

Clinical Features

Signs suggestive of ureteral injury include flank ecchymosis and occasionally gross hematuria with blunt trauma, and fractures of the transverse process of lumbar vertebrae are often seen. However, hematuria is seen in only half of patients and is usually microscopic. In addition, because over 20% of patients with ureteral injuries and blunt trauma have multisystem trauma with bony injuries (such as, pelvic and vertebral fractures) and hollow viscous injuries, they may not have complaints specific to the ureter, despite having a significant injury. Penetrating injuries of the ureter are often associated with injuries to the iliac vessels, which are often life-threatening. Given their subtle presentation, ureteral injuries do not declare themselves until later when patients present with sepsis (from urinary extravasation), hydronephrosis from obstruction, or a urinary fistula.3

Differential Diagnosis

Blunt trauma affecting the ureter can lead to stretching and resultant hematomas or, if more severe, partial or complete disruption of the ureteral wall. Penetrating injuries involving the ureter generally result in complete or partial transection.5

Diagnostic Testing

Hematuria is not a reliable indicator of ureteral trauma, because it is present in only 50% of patients. Blunt ureteral injury is rare, however, and further diagnostic evaluation for ureteral injury is reserved for patients with unexplained persistent hematuria or evidence of injury adjacent to the ureter, such as retroperitoneal vascular injury, vertebral fractures, or penetrating injuries near the flank. The best modality for diagnosing ureteral injury is IV contrast CT scan.1

IV pyelography/urography and retrograde pyelography were once used to diagnose ureteral injury, but they have been supplanted by CT scanning (Fig. 40.11). CT scan performed immediately after the administration of IV contrast can potentially miss ureteral injuries, and 10 minute delayed imaging (allowing for contrast to enter and pass through the ureter from the collecting system) is recommended. CT findings of ureteral injury include contrast extravasation, a delayed pyelogram, hydronephrosis, or lack of contrast distal to the ureteral injury.1 Additionally, the presence of a transverse process fracture, perinephric stranding or hematomas, and low-density retroperitoneal fluid (representing urinary extravasation) should raise the concern for ureteral injury. If delayed CT imaging was not initially performed but ureteral injury is suggested by these findings, a plain film of the abdomen can be obtained 30 minutes after CT to assess for contrast extravasation into the pelvis. Alternatively, retrograde pyelography can be performed.35

Management

With minor injuries including contusions and partial lacerations, ureteral stenting is typically sufficient. However, debridement with anastomosis may be necessary with loss of a segment.3 Additional options include percutaneous nephrostomy for unstable patients and ureteral reimplantation into the bladder. Nephrectomy is rare but sometimes necessary with more proximal injuries.35

Almost one-quarter of all patients develop a complication after ureteral injury, which are rarely life threatening but can occasionally lead to the loss of the affected kidney. Urinary leaks leading to sepsis or fistulas, as well as strictures, are among the most common complications, and are frequently seen when diagnosis of the initial injury is delayed.35

BLADDER TRAUMA

Clinical Features

Unlike injuries to the ureter, hematuria is the hallmark of a bladder injury, with gross hematuria noted in 72% of patients with blunt trauma to the bladder, and up to 95% of patients with penetrating bladder trauma.6 Other signs and symptoms include abdominal tenderness (approximately 60% of patients), blood at the urethral meatus, the inability to void, and ecchymosis in the perineum, thigh, or abdomen.15

Differential Diagnosis

Differentiating intraperitoneal from EBR is of utmost importance. Intraperitoneal injuries are most often caused by significant blunt force abdominal trauma in a patient with a distended bladder. Extraperitoneal injuries are usually associated with some form of pelvic trauma. Bladder injuries themselves can range from mural hematomas to through-and-through disruptions of the bladder wall, resulting in rupture.35

Diagnostic Testing

Other than urinalysis, laboratory evaluation is not useful in diagnosis of bladder injury.1 Gross hematuria is present in the majority of cases; those without gross hematuria will have microscopic hematuria. High energy pelvic fractures, such as symphysis diastasis and displaced obturator ring fractures, should also raise the suspicion of bladder injury.35

All patients with gross hematuria and pelvic fracture should undergo cystographic imaging, due to the high likelihood of
bladder injury. Imaging is also indicated for patients with microscopic hematuria and either pelvic ring or obturator fractures, or with penetrating trauma to the pelvis. CT scan performed with IV contrast alone does not sufficiently distend the bladder to evaluate for mural defects, leading to false negatives, and thus retrograde “stress” cystography must be performed. This involves diluting 30 mL of water-soluble ionic contrast in a 500 mL bag of warmed saline. Approximately 300 to 400 mL of this solution is then introduced into the bladder via a Foley catheter using gravity. Foley catheterization should not be performed unless the clinician is confident that urethral injury is not present (see discussion following). By distending the bladder, thrombi that may have formed along the bladder wall are dislodged, allowing for urinary extravasation. Images are then acquired to assess for rupture. Conventional cystography can assess for urinary extravasation (Figs. 40.12 and 40.13). However, CT is more sensitive (95%) and can evaluate for foreign body involvement from fractures or even bladder neck injuries. EBR may demonstrate a “molar tooth” appearance on cystography, which represents contrast tracking along the pelvic fascial planes (Fig. 40.14), whereas IBR reveals contrast material outlining the intraperitoneal structures (Fig. 40.15).

Bedside ultrasonography has not been fully studied to assess for bladder rupture, although it does show promise (Fig. 40.16). As with any evaluation using ultrasound, this technique is highly operator dependent, and findings are not necessarily specific.

Management

The distinction between EBR and IBR is important, because the management differs. Contusions and extraperitoneal injuries due to blunt trauma are typically managed conservatively with Foley catheterization, unless they are complicated by other intra-abdominal injuries, bladder neck injuries, bone fragments in the bladder wall, or if open reduction is performed on an associated pelvic fracture. In contrast, given the extremely low likelihood of IBR and penetrating injuries healing with conservative therapy, almost all patients with these types of injuries are taken to the operating room for exploration and repair. Without surgery, there is an extremely high likelihood of complications, which include infections and fistula formation.

Compared to patients with pelvic fracture alone, a concomitant bladder injury is associated with a 75% increase in mortality. Due to the significant mechanism needed to cause an IBR, these injuries are associated with an approximate 20% mortality, which is twelve times more than is seen with isolated EBR. Operative repair decreases the mortality risk by nearly 60%. Additionally, intraperitoneal urinary extravasation can lead to delayed morbidity and mortality due to resultant infections, as well as ileus and chemical peritonitis. Extraperitoneal injuries can lead to fistula formation or infections as well but occur in the minority of cases. Penetrating rectal injuries leading to bladder involvement can result in abscess, bladder stones, urethral strictures, and fistulae. The high likelihood of potential complications underscores the importance of performing retrograde cystography with an adequate amount of volume in order to diagnose all cases of bladder injury.

URETHRAL TRAUMA

Clinical Features

The “classic” presentation of posterior urethral injury includes blood at the urethral meatus, urinary retention, and a “high-riding” prostate on digital rectal examination (DRE). However, DRE is not a sensitive test, because the prostate can be obscured by a pelvic hematoma, which is common after pelvic fractures. Therefore, DRE should be focused on detecting rectal injuries, and it should not be used to diagnose urethral injury. Other findings include swelling or ecchymosis of the perineum or penis (including “butterfly bruising” seen with anterior injuries that violate Buck’s fascia; Fig. 40.17) and a distended bladder due to the inability to void.

Blood at the urethral meatus is the most common sign, occurring in up to 90% of posterior injuries and 75% of anterior injuries. As a result, absence of blood at the meatus and the lack of a genital hematoma, bruising, or swelling decrease the likelihood of urethral injury. The degree of hematuria is not correlated with the
Fig. 40.14. Computed tomography (CT) cystography images from a complex extraperitoneal bladder rupture (EBR). A, The arrowhead overlying the bladder points to the location of extravasation into the perivesicular spaces. B and C, Contrast extravasation continues along the left retroperitoneum, extending into the perirenal space. D, The rupture was likely caused by the displaced ramus fracture fragment which is seen violating the bladder wall. There is an associated lumbar spine fracture noted in C. (From Avery LL, Scheinfeld MH: Imaging of male pelvic trauma. Radiol Clin North Am 50:1201–1217, 2012.)

Fig. 40.15. Computed tomography (CT) images from a patient with intraperitoneal bladder rupture (IBR). A and B, Images acquired immediately after intravenous (IV) contrast administration reveal fluid around the liver and spleen, as well as clot within the bladder and left anterior bladder wall. CT cystography reveals intraperitoneal extravasation of contrast (C) with a disruption of the dome of the diaphragm (D). (From Avery LL, Scheinfeld MH: Imaging of male pelvic trauma. Radiol Clin North Am 50:1201–1217, 2012.)
CHAPTER 40  Genitourinary System

Diagnostic Testing

Retrograde urethrography (RUG) is the gold standard for diagnosing urethral injuries, and it should be performed if there is blood at the urethral meatus, or other findings consistent with urethral injury (eg, perineal or pelvic ecchymosis or swelling), prior to bladder catheterization (Fig. 40.18). The technique for performing a RUG is detailed in Box 40.1 and depicted in Figure 40.19. A scout film that can demonstrate preexisting calcifications is important to avoid false positive diagnoses, and then it can be compared to post-contrast images. Urethrography can determine the location (anterior and posterior) and extent (partial versus complete) of the injury, and it has excellent sensitivity and specificity. Figure 40.20 depicts a potential schematic of a urethral injury with the resultant RUG image. If a urinary catheter has already been placed, a pericatheter RUG can be performed by introducing a 3 Fr catheter into the fossa navicularis and then introducing a small amount of contrast.

CT scan with IV contrast only carries a sensitivity of 88% and specificity of 79%, confirming RUG as the gold standard. Ultrasonography and magnetic resonance imaging (MRI) also have limited utility in the diagnosis of urethral injury.

Management

The immediate goal with urethral injury is to secure catheter drainage of the bladder. Instrumenting a partially disrupted urethra with a Foley catheter can lead to complete disruption of the urethra. Additionally, continued extravasation of urine through a urethral laceration can lead to infection. Therefore, if a urethral injury is diagnosed, a suprapubic catheter should be placed as soon as possible. Figure 40.21 details this procedure, which should be performed under ultrasound guidance, if possible, to avoid injury to the bowels.

After suprapubic drainage is established, the surgical management of urethral injuries can be delayed in favor of treating other life-threatening injuries, except in the case of penetrating injuries or concomitant bladder neck injuries, which should be explored.

Differential Diagnosis

Mild blunt-force injuries to the urethra can result in stretching of the urethra or a contusion of the wall. More severe injuries include partial or complete disruption of the wall. Penetrating injuries usually result in some sort of disruption of the lumen of the urethra. If complete disruption occurs, the amount of urethral separation is important, because more than 2 cm of disruption carries a worse prognosis.

degree of injury; in fact, a transection can cause a minimal amount of microscopic hematuria, whereas a contusion can induce copious bleeding.
BOX 40.1

Technique for Performing Retrograde Urethrography

1. A 16-Fr or 18-Fr Foley catheter or a hysterosalpingogram catheter is flushed with radiopaque contrast to avoid air bubbles.
2. The glans penis and urethral meatus are cleaned with antiseptic.
3. The catheter is inserted into the penis, and the balloon is partially inflated (1 to 2 mL) in the fossa navicularis.
4. The penis is then pulled laterally to straighten the urethra under moderate traction.
5. A precontrast “scout” image is obtained, because prostatic calcifications may be confused for extravasated contrast.
6. Under fluoroscopic visualization, 20 to 30 mL of contrast is injected with the goal of filling the entire urethra.
7. If spasm of the external sphincter prevents posterior urethral filling, slow, gentle pressure may allow opacification.
8. Static images are obtained to demonstrate the identified pathologic condition.

Fig. 40.19. Christmas tree adapter on the end of a 60-mL syringe has been gently placed inside the fossa navicularis in preparation for retrograde urethrography (RUG).

Fig. 40.20. Schematic representation of disruption of the membranous urethra (A) with retrograde urethrogram (B) revealing contrast extravasation above the urogenital diaphragm. (From Nicola R, Menias CO, Mellnick V, et al: Sports-related genitourinary trauma in the male athlete. Emerg Radiol 22[2]:157–168, 2015.)

and debrided immediately. Delayed repair allows time for inflammation to decrease and is associated with lower rates of erectile dysfunction, urinary incontinence, and stricture formation.

Complications of urethral injury include urethral stricture, urinary incontinence, and erectile dysfunction, which affects almost half of all men suffering urethral injuries. Almost half of all children with pelvic fractures and associated urethral injury will exhibit erectile dysfunction at puberty. An even higher number is seen in patients with pubic diastasis. The cause of erectile dysfunction is thought to be neurogenic in most cases, but it can be vasogenic or mixed in some cases. In children, a higher risk is seen with urethral gap lengths more than 2.5 cm and lateral prostatic displacement. A higher rate of future stress incontinence is seen in women with urethral trauma.

GENITAL TRAUMA

Clinical Features

Patients with scrotal injuries may present immediately with swelling and pain, but note that patients with scrotal injuries often do not present acutely; in one study, patients had median presentation durations of 3 days. Due to swelling, it is often difficult to distinguish between the different types of testicular injury on examination. Blunt force of at least 50 kg is needed to cause a rupture of the tunica albuginea with extrusion of the seminiferous tubules, resulting in testicular fracture.

Penile injuries result in pain, swelling, and ecchymosis. In the setting of blunt or penetrating injuries, blood at the urethral meatus, gross hematuria, or the inability to void suggest a concomitant urethral injury. False penile fractures present with the swelling and ecchymosis that is typically seen with penile fractures, but patients typically experience a more gradual detumescence and do not typically notice the popping sound that accompanies most cases of penile fracture (Fig. 40.22). However, it is very difficult to make a clinical distinction between true and false penile fractures, and many of these cases still require exploration.

True penile fractures are relatively uncommon but are also likely underreported. It is defined as a rupture of the tunica albuginea surrounding any of the three corpora of the penis. The tunica albuginea stretches when the penis is erect, making it thin and inflexible, and thus more prone to rupture with lateral...
bending. In the Western hemisphere, penile fracture most often occurs when the penis slips out of the vagina during intercourse and is accidentally thrust against the perineum or pubic symphysis. However, in the Mediterranean and Middle-East, the most common cause is *taghaandan*—where the erect penis is forcibly pushed down to achieve detumescence. Penile fractures are associated with urethral injuries in 10% to 20% of cases, and urethral injuries are more likely in cases of bilateral corporal fractures or when blood is noted at the urethral meatus (Fig. 40.23). Patients with penile fracture experience immediate pain with
Diagnostic Testing

Due to the external nature of the genitalia, diagnoses of genital trauma are usually made clinically, as opposed to other genitourinary trauma, which often require imaging studies. Scrotal injuries typically present with swelling, pain, bruising, lacerations, and/or skin loss. However, due to swelling, the examination can be limited.86 Laboratory studies are not helpful, except for diagnosing concomitant injuries.

Imaging

Scrotal ultrasound is the imaging modality of choice when evaluating for testicular injury because of its accuracy, as well as its availability. The ability to evaluate flow using Doppler is extremely useful when determining viability and vulnerability of tissue. Along with testicular rupture, ultrasound can diagnose fractures, hematomas, hematocoeles, and contusions. MRI can be used but is less practical given its long acquisition time and the limited availability. For testicular rupture, the sensitivity of ultrasonography approaches 100% and should focus on testicular echotexture, as well as the contour of the testicle. Irregularities of the contour or a discontinuity of the tunica albuginea suggest testicular rupture (Fig. 40.25).
Management

Testicular and penile fractures require prompt urological consultation and surgery, and they are discussed in more detail later. With any type of penetrating injury to the scrotum or penis, surgical exploration is usually indicated to evaluate for injuries to deeper structures that could result in significant morbidity, unless the injury is extremely superficial.

Penile surgical exploration involves degloving the entire penis to allow for visualization of all structures. Prognosis after penile fractures is generally good, but cosmetic abnormalities can occur, even with prompt surgical repair.

For testicular rupture, operative intervention focuses on débriding nonviable tissue and closing the tunica albuginea, although orchiectomy is performed if the testicle is deemed non-viable. The rate of orchiectomy is low (10% to 20%) if exploration is performed within 72 hours, but if there is significant delay, the rate is significantly higher (45%). The goal of surgery for testicular injuries is testicular salvage, although penetrating injuries still result in a 35% rate of orchiectomy due to testicular necrosis or unhealthy parenchyma.

Typically, small scrotal hematomas respond well to rest and nonsteroidal antiinflammatory drug (NSAID) therapy. However, scrotal hematoceles and expanding or large scrotal hematomas may lead to testicular ischemia due to local pressure effects on blood vessels and, thus, may also require exploration. Reduction of testicular dislocations should be attempted by applying gentle caudad pressure following the course of the spermatic cord. However, even if reduction is successful, ultrasound should be performed to evaluate for vascular compromise, and patients usually require future operative intervention in the form of orchiopexy to prevent testicular torsion.

Amputations of either the testicles or penis require immediate surgical evaluation. In the interim, the amputated part should be wrapped in saline soaked gauze and then placed in a sealed bag, which can then be placed in another bag that is filled with ice. The amputated part should never be placed directly on ice. Direct pressure is usually adequate to achieve hemostasis.

Ultrasound is also the preferred modality for penile imaging. It can diagnose penile fracture, but can also be used to evaluate the blood flow in penile arteries and veins. Unlike scrotal ultrasound, however, penile ultrasound is used less often, as the diagnosis of penile fracture is usually made clinically. Due to the extensive exploration required to evaluate for penile fracture, however, ultrasound is gaining more popularity because it can reveal a defect in the tunica albuginea with extruding hematoma, as well as assess blood flow in the arteries and veins (Fig. 40.26).

RUG should be considered if there are concerns about concomitant urethral injury (Fig. 40.27).
Injuries to the female genitalia may need the operating room for an examination (and repair) under anesthesia, or for extensive lacerations involving the labia, perineum, and posterior fourchette. Again, the threshold for an examination under anesthesia should be extremely low, especially in the pediatric population.

Zipper injuries should be evaluated thoroughly for underlying trauma to the penis (or scrotum when involved). If the zipper is stuck, the cloth between the interlocked dentition of the zipper can be cut. However, if the zipper is caught in the buckle of the fastener, unzipping can be attempted, and mineral oil may help with removal. However, if this proves unsuccessful, the medial bar of the zipper can be cut with bone or wire cutters to separate the face plates. Sometimes, however, circumcision or an elliptical incision of the penile skin must be performed to achieve release.

Burns to the external genitalia are usually not seen in isolation, and the thin skin of the penis makes it quite vulnerable to full-thickness burns. Patients with burns that are not extremely superficial should be evaluated at a burn center as soon as possible.

More than 10% of these patients will need surgical débridement. Superficial burns can be treated with topical therapies. Occasionally, patients will present with constricting rings that have created local ischemia and swelling, and attempts at removal should be made as quickly as possible to prevent tissue necrosis from ischemia.

Scrotal injuries leading to orchiectomy can be a source of infertility but can also alter hormonal function. Other complications include voiding dysfunction and erectile dysfunction. Many of the complications of penile injury are cosmetic in nature, including penile curvature and plaque or nodule formation superficially after penile fracture, but the likelihood is significantly decreased with surgery. Still, urethral injury can lead to stricture formation, penile abscess, permanent curvature, and painful erections, even if repair is successful. A delay in diagnosing female genital injury can lead to urinary or fecal incontinence, chronic fissures, rectovaginal fistula, or even vaginal stenosis, highlighting the importance of a thorough physical examination.

**KEY CONCEPTS**

- Microscopic or gross hematuria is suggestive of genitourinary trauma; however, the degree of hematuria does not correlate well with the severity of injury.
- The kidney is the most frequently injured genitourinary organ, and imaging should be considered in patients with gross hematuria or microscopic hematuria with hemodynamic instability.
- Delayed CT images after IV contrast should be obtained in patients with mechanism or findings suggestive of ureteral trauma. Blunt ureteral trauma is rare.
- CT scan with IV contrast is not sensitive for diagnosing bladder injury, and retrograde cystography should be obtained if there is any concern to allow proper distention of the bladder to allow for urinary extravasation.
- Pelvic fractures associated with hematuria strongly suggest urethral injury.
- Retrograde urethrography (RUG) should be performed in patients with pelvic fractures and hematuria, perineal ecchymosis or swelling, or those with blood at the urethral meatus, because passage of a Foley catheter blindly in these settings can worsen a preexisting urethral injury.
- Genital injury is rarely life threatening, but prompt diagnosis and evaluation is necessary to decrease the likelihood of future morbidity in these patients.

CHAPTER 40: QUESTIONS & ANSWERS
40.1. All of the following are associated with clinically
significant blunt renal injuries in adult patients and would
warrant further evaluation, except:
A. A sudden decelerating mechanism of injury in a
patient without microhematuria
B. A sudden decelerating mechanism of injury in a
patient without shock
C. Gross hematuria
D. Microscopic hematuria
E. Microscopic hematuria in a patient with shock

Answer: D. Renal injury requiring intervention is rare in the
absence of gross hematuria or shock. Gross hematuria warrants
careful evaluation for significant genitourinary injury, although
the degree of hematuria does not necessarily correlate with the
degree or grade of injury and significant genitourinary trauma
can occur without hematuria. Microscopic hematuria in a blunt
trauma patient without shock is not an indication for renal
imaging, even if there is evidence of local trauma (eg, costovertebral angle tenderness or localized ecchymosis). Although renal
injury may uncommonly be identified on imaging for these

434.e1


40.2. A 27-year-old male presents after a motor vehicle collision complaining of abdominal pain. He was the restrained driver of a car struck on the driver’s side by a delivery truck. His vital signs are blood pressure 118/72, heart rate 70 beats per minute, and respiratory rate 16 breaths per minute. Physical examination reveals left upper quadrant abdominal tenderness without guarding or rebound tenderness. There is no blood at the urethral meatus or scrotal hematoma. A Foley catheter is placed without difficulty and drains gross blood. A radiograph of the pelvis reveals fractures of the left superior and inferior pubic rami, and a focused assessment with sonography in trauma (FAST) examination reveals free fluid in the splenorenal pouch. Which of the following diagnostic strategies is most appropriate?

A. Intravenous (IV) contrast-enhanced computed tomography (CT) of the abdomen and pelvis with delayed images of the bladder after clamping the Foley catheter to allow the IV contrast to collect in the bladder
B. IV contrast-enhanced CT of the abdomen and pelvis with delayed images of the renal collecting system
C. IV contrast-enhanced CT of the abdomen and pelvis and retrograde CT cystogram
D. IV contrast-enhanced CT of the abdomen and pelvis and retrograde urethrogram
E. Retrograde cystogram followed by IV pyelogram

Answer: C. This patient has clinical features concerning for several possible injuries, including a splenic laceration, renal injury, and bladder rupture. Significant urethral injury is less likely, given the examination findings and ease of Foley catheter placement. Because the patient is stable without apparent indication for laparotomy, the most appropriate diagnostic evaluation would be IV contrast-enhanced CT of the abdomen and pelvis and retrograde CT cystogram. The former will evaluate for solid organ injury and the latter for bladder rupture. It is essential that cystography not be done in an antegrade fashion, because such studies (eg, injecting IV contrast material, clamping the Foley catheter, and allowing the examination to depend on antegrade filling of the bladder from renal excretion of progressively dilute contrast material) may produce incomplete and spurious findings because of inadequate distention of the bladder.

40.3. A 72-year-old male presents with flank and pelvic pain after he slipped and fell on an icy sidewalk. His examination reveals normal vital signs and abrasions over the left flank and left iliac crest and is otherwise unremarkable. He has grossly clear urine, but a urinalysis reveals 25 red blood cells per high-power field. Radiographs of the pelvis and hips reveal no fracture, and the patient is able to ambulate without difficulty. What is the most appropriate next step?

A. Obtain a renal ultrasound scan.
B. Obtain an IV contrast-enhanced CT of the abdomen and pelvis.
C. Perform a retrograde cystogram.
D. Perform a retrograde urethrogram.
E. Treat the patient’s pain and discharge him home with outpatient urology follow-up in 1 week.

Answer: E. A significant genitourinary injury is unlikely, given the patient’s history, physical examination, and urine findings. However, outpatient urology follow-up until microhematuria has cleared is advisable to be certain that it does not represent another more serious underlying (nontraumatic) condition.

40.4. A 35-year-old female presents after being stabbed with an ice pick during a robbery. Her examination is normal except for a 0.5-cm, hemostatic wound to the right flank at the level of the second lumbar vertebrae. Bedside ultrasonography reveals no free intra-abdominal fluid. Her urinalysis does not contain blood. What is the most appropriate next step?

A. Obtain a renal ultrasound scan.
B. Obtain an IV contrast-enhanced CT of the abdomen and pelvis, with additional images of the renal collecting system 10 minutes after contrast injection.
C. Perform a retrograde cystogram.
D. Perform a retrograde urethrogram.
E. Treat the patient’s pain, counsel her on appropriate wound care, and discharge her home with outpatient urology follow-up in 1 week.

Answer: B. In cases of penetrating renal trauma, the presence or absence of hematuria is not a reliable predictor of upper urinary tract injury. The location of the penetrating injury in relation to the urinary tract is the most important determining factor in deciding the need for radiographic investigation. Therefore, the absence of hematuria in a patient with a gunshot or stab wound in proximity to the urinary tract does not eliminate the need for IV contrast-enhanced CT as the initial diagnostic examination. Significant injuries to the kidney and ureter may occur in penetrating trauma without hematuria. Additional images obtained at 10 minutes after contrast injection are indicated to evaluate for delayed contrast extravasation and to maximize the sensitivity of the study.

40.5. A 25-year-old male presents after an unfortunate incident resulting in a scrotal injury and a left testicle that was traumatically amputated (the patient brings the amputated testicle with him in a towel). All of the following would be indicated, except:

A. Analgesics for the patient
B. Emergent urological consultation
C. Place the amputated testicle directly on ice
D. Prepare the patient for possible operative exploration by the surgeon
E. Wrap the amputated testicle in saline soaked gauze

Answer: C. Amputations of either the testicles or penis require immediate surgical evaluation. In the interim, the amputated part should be wrapped in saline-soaked gauze, and then placed in a sealed bag, which can then be placed in another bag that is filled with ice. The amputated part should never be placed directly on ice. Direct pressure is usually adequate to achieve hemostasis.

40.6. A 30-year-old female presents after blunt abdominal trauma after a motor vehicle collision, and an ultrasound demonstrates free fluid. You suspect a bladder rupture. A true statement about this entity includes which of the following:

A. A bladder contusion may be successfully managed with Foley catheterization drainage.

Answer: A. Bladder contusion may be successfully managed with Foley catheterization drainage.
B. Extraperitoneal bladder injuries are typically managed with surgical intervention.
C. It is unimportant to distinguish an intraperitoneal from an extraperitoneal bladder rupture (EBR).
D. Most patients with an intraperitoneal bladder rupture (IBR) will resolve with Foley catheter drainage.
E. Most penetrating bladder injuries will resolve with Foley catheter drainage.

**Answer: A.** The distinction between EBR and IBR is important, because the management differs. Contusions and extraperitoneal injuries due to blunt trauma are typically managed conservatively with Foley catheterization, unless they are complicated by other intra-abdominal injuries, bladder neck injuries, bone fragments in the bladder wall, or if open reduction is performed on an associated pelvic fracture. In contrast, given the extremely low likelihood of IBR and penetrating injuries healing with conservative therapy, almost all patients with these types of injuries are taken to the operating room for exploration and repair. Without surgery, there is an extremely high likelihood of complications, which include infections and fistula formation.
PRINCIPLES

Background and Importance
Injury to the major peripheral arteries or veins may not always be life-threatening, but it invariably poses a threat to the viability of the affected limb. Historically, due to the rapidity of exsanguina-
tion, injury to major vessels was often fatal in the field; and most patients who survived to hospital arrival had relatively minor vascular injuries. However, with the advent of modern emergency medical service (EMS) systems with advanced extrication methods and rapid transport, more patients with major vascular injuries are reaching the emergency department (ED) alive. In addition, the incidence of both penetrating injuries from interpersonal violence and blunt injuries from motor vehicle–related trauma has increased dramatically over the past 50 years. Consequently, emergency clinicians are frequently confronted with critically ill patients harboring overt (or occult) peripheral vascular injuries.

Management of these vascular injuries has also evolved, with advances in diagnostic methods and surgical techniques. Treatment of vascular injuries before and during World War II resulted in limb amputation rates of 50% to 75%. Advances during the Korean and Vietnam wars reduced amputation rates to 5% to 15%, which approach the current rates of amputation for civilian injuries.

Tremendous progress has also been achieved in diagnostic and therapeutic techniques for dealing with peripheral vascular inju-
ries, and several noninvasive diagnostic modalities have emerged as accurate alternatives to surgical exploration and angiography. These techniques are easily used in the ED, and the goal of timely detection and repair of serious vascular injuries is achievable in the majority of cases.

Peripheral vascular injuries are divided almost equally between blunt and penetrating mechanisms. In the United States, up to 90% of these injuries are a result of penetrating wounds, mainly because of the high rate of penetrating trauma in inner-city urban areas. Major venous injuries are present in up to 50% of gunshot wound cases, and more than 80% of these have associated arterial injuries. In addition, due to the increased use of percutaneous endovascular diagnostic and therapeutic procedures, the incidence of iatrogenic vascular injuries has increased and accounts for up to one-third of all cases in some series.

Anatomy and Physiology
The major vessels and their relevant anatomy are described in the following sections (Figs. 41.1 and 41.2).

Upper Extremity
The right subclavian artery arises from the brachiocephalic artery, and the left arises from the arch of the aorta. From their origin, they course posterior and inferior to the clavicles to the outer margins of the first ribs, where they become the axillary artery and vein. The left subclavian artery rises higher than the right and extends into the root of the neck.

The axillary artery courses from the lateral border of the first rib to the inferior border of the teres major muscle, where it becomes the brachial artery. The axillary vein runs medial to the artery. Due to the extensive anastomotic arterial connections around the shoulder joint, up to half of patients with axillary artery injuries will have palpable pulses as a result of collateral circulation. Because of the close proximity of the brachial plexus and the axillary vessels, significant denervation of the upper extremity can occur.

The brachial artery begins at the lower border of the teres major muscle and divides into the radial and ulnar arteries at the level of the proximal aspect of the radial head. The median and ulnar nerves and the basilic vein are in close proximity to the brachial artery. The profunda brachii artery is a major branch that arises slightly after the origin of the brachial artery and often contributes good collateral flow if the brachial artery is injured distal to this branch point.

The radial artery originates in the cubital fossa and runs superficially to the distal end of the radius, where it ultimately joins the deep branch of the ulnar artery to form the deep palmar arch of the hand. The ulnar artery begins in the cubital fossa and runs with the ulnar nerve anterior to the flexor retinaculum, at which point it joins the radial artery to form the superficial palmar arch of the hand.

Lower Extremity
The external iliac vessels become the common femoral vessels at the inguinal ligament. After giving off the profunda femoris artery, the femoral artery continues as the superficial femoral artery almost vertically to the adductor tubercle of the femur and enters the popliteal fossa as the popliteal artery. Extensive proximal collaterals are present around the hip joint, including the gluteal, obturator, and pudendal branches of the iliac artery.

The popliteal artery gives off the genicular branches in the popliteal fossa and then divides into the anterior and posterior tibial arteries at the lower border of the popliteus muscle. The popliteal artery arises from the posterior tibial artery slightly after its origin. The anterior and posterior tibial arteries and the peroneal artery form the trifurcation of the popliteal artery, and each runs with a corresponding vein and nerve in different compartments of the leg.

The popliteal artery divides into three branches—the anterior and posterior tibial and the peroneal arteries—at the inferior margin of the popliteal fossa. Injuries below the trifurcation at the knee may need repair if hard signs of arterial injury are apparent in the foot or if two of the three arteries are occluded. The most common blunt trauma cause of popliteal artery injury is a posterior knee dislocation in which bony elements directly lacerate or cause thrombosis of the artery. Anterior knee dislocations may cause excessive stretch on the popliteal vessels resulting in arterial
thrombosis, but this injury is relatively rare. Up to one-third of knee dislocations result in popliteal artery injury. Twenty-five percent of cases have an associated injury to the peroneal and posterior tibial nerves. A knee dislocation may reduce spontaneously, leaving little evidence of the original trauma, particularly in obtunded patients.

Pathophysiology

Blunt and penetrating types of trauma result in similar spectra of vascular injuries, although their mechanisms of injury differ. Although blunt vascular injuries are less common than penetrating injuries, they are often more severe and more commonly result in amputation because of associated injuries to nerves, bone, and soft tissue. Certain mechanisms of injury, such as animal bites that crush and lacerate vessels, can involve both penetrating and blunt mechanisms.

Penetrating Trauma

Gunshot wounds can cause direct arterial lacerations or transections, in addition to concussive injuries distal to the track of the bullet. These latter injuries tend to be tears in the intima of an artery, with subsequent thromboses that may not become apparent for hours to months after the injury. Bullets may ricochet off bone, making predicting trajectories less accurate than with stab wounds.

Stab wounds cause vascular injuries by completely or partially transecting vessels. Partial laceration of an artery may produce few symptoms of arterial insufficiency on initial evaluation but result in delayed complications. The vascular structures at risk can be predicted more reliably with stab wounds than with gunshot wounds by taking into consideration the anatomic location, causative implement, depth, and direction of the wound.

Shotgun wounds are less common than gunshot or stab wounds, but they can cause injuries varying from minor soft tissue wounds to massive destruction of soft tissue and bone, depending primarily on the range from which the shotgun was fired. The presence of multiple missiles ranging from 9 or 10 (buckshot) to dozens (birdshot) also complicates the evaluation of these injuries because of the many potential sites of potential vascular injury. In addition, close-range shotgun wounds (<3 yards) can cause significant blunt trauma to blood vessels, as well as a higher rate of bone and nerve injury than might occur with gunshot wounds. Migration of pellets or bullets proximally through the venous system to the heart, or migration through an artery with subsequent distal occlusion, has been reported frequently as a delayed complication.3,4

Blunt Trauma

Blunt injury involves either avulsion forces that can stretch vessels beyond their capacities or direct crushing injuries that disrupt vessel walls. In addition, fracture fragments resulting from blunt extremity trauma can lacerate or entrap vessels. These vascular injuries can range from small intimal tears to complete avulsions of arteries and nerves. Open avulsion injury of a limb is particularly severe because the skin, which is very pliable, is the final structure to tear. Once torn, it is inevitable that vessels and nerves will tear as well. Vascular injuries should also be suspected in patients with massive soft tissue avulsions or crush injuries, displaced long bone fractures, electrical or lightning injuries, and severe burns, as well as in those with compartment syndrome from trauma or prolonged immobilization as a result of stroke, coma, drug overdose, or other causes. Bites that are inflicted by large animals, such as dogs used by law enforcement, are particularly prone to arterial injury and wound complications.5

Collateral
circulation may continue to perfuse the limb, but injuries that occur proximal to the collateral branch point—or that involve both the main trunk and collateral branches—will preclude adequate flow.

Distal ischemia results from the inability of tissues to continue aerobic metabolism. Eventually, anaerobic metabolism consumes all substrate, thereby resulting in the accumulation of lactic acid. As ischemia progresses, cellular integrity is lost and irreversible cell death occurs. A vicious cycle of tissue edema and further impairment of the blood supply occurs. When no specific measures are taken to cool the limb, it is said that the limb is undergoing “warm ischemia” at ambient temperature. After 6 hours of complete warm ischemia, 10% of patients will have irreversible damage; by 12 hours, 90% will have irreversible damage. Artificially cooling the limb to near freezing temperature (“cold ischemia”) will reduce the metabolic demands and greatly prolong the tissue’s tolerance of ischemia to 24 hours or more.

Two main types of vascular injury can result from trauma: occlusive injuries (transections, thromboses, and reversible spasm), in which all perfusion distal to the occlusion is lost, and nonocclusive injuries (intimal flaps, dissections, arteriovenous fistulae [AVF], and pseudoaneurysms), which include mechanical defects to vessel walls that may or may not lead to decreased distal blood flow.

Complete Occlusive Injury

**Transection.** The most common vascular injury is complete transection, in which distal flow is effectively eliminated. Cleanly transected arteries will often retract and undergo spasm to minimize blood loss. With longitudinal arterial lacerations and venous injuries, blood loss cannot be minimized by this physiologic response, and therefore tend to result in greater blood loss. Pulsatile bleeding may quickly lead to exsanguinating hemorrhage and shock.

**Thrombosis.** Intraluminal thrombosis (Fig. 41.3) may occur in an injured artery acutely (within 24 hours) or may be delayed for many months. Acute thrombosis is initiated by stasis resulting from compression of the artery or from a disruption in the intima of an artery that becomes a nidus for thrombus formation. As the thrombus propagates, complete occlusion of the vessel can occur. Delayed thrombosis can occur months to years after injury if the injured vessel heals with stricture formation, resulting in decreased distal flow, followed by stasis and clot formation.

**Reversible Arterial Spasm.** The precise cause and incidence of significant reversible arterial spasm after trauma are unknown. In the case of arterial transection, arterial spasm is beneficial and limits hemorrhage. In other cases, however, the segmental arterial spasm occurs at some distance from the site of traumatic injury and can produce severe distal ischemia. Arterial spasm is particularly common in children. In many series, segmental arterial spasm is the most common arteriographic finding (Fig. 41.4). However, symptoms of ischemia should never be assumed to be a result of arterial spasm; that diagnosis is based on arteriographic results only.

Nonocclusive Injuries

**Intimal Flap.** An intimal flap occurs when there is a break in the vessel intima, generally from excessive stretch or concussive forces. Although flow is not altered by small flaps and the associated soft tissue wounds often appear benign initially, these intimal flaps may become a nidus for thrombosis that can occur hours to months after the initial injury.

**Pseudoaneurysm.** A true aneurysm contains all three layers of the vessel wall (intima, media, and adventitia) and rarely is caused by trauma. A pseudoaneurysm is formed following a tear in a vessel wherein the hemorrhage is contained by surrounding fascia and the resulting hematoma is gradually encased by a capsule of fibrous tissue, analogous in consistency to the adventitia of a normal vessel (Fig. 41.5). Because it is relatively thin walled, rupture of a pseudoaneurysm is a distinct possibility. In addition, because its diameter inevitably expands under arterial pressure

over days to months, compression of adjacent tissue may result in neuropathy, venous obstruction with resultant peripheral edema and venous thrombosis, and even erosion into adjacent bone. The cavity of a pseudoaneurysm is in direct communication with the lumen of the vessel, so embolization of mural clots may produce distal arterial occlusion. Pseudoaneurysms may be diagnosed months to years after an injury when patients manifest symptoms of compression neuropathy or peripheral arterial embolism or for investigation of a soft tissue “tumor” that represents the growing aneurysm.

Arteriovenous Fistula. An AVF is formed when both an artery and an adjacent vein are injured. Higher-pressure arterial flow is directed into the lower-pressure vein, thereby diverting the blood supply to distal tissues and engorging the distal veins. Because the aperture of the fistula is often relatively narrow and thus results in turbulent flow, a bruit and palpable thrill are common diagnostic findings. Symptoms are primarily those of distal ischemia, but rarely, high-output congestive heart failure may occur when large central vessels are involved. Symptoms are often delayed for months, because it takes time for the fistula to mature.

Compartment Syndrome. Compartment syndrome is most common after crush injury or a long bone fracture but may also be seen after reperfusion of an ischemic limb. Initially, blood flow is diminished and the injury is considered nonocclusive. Progressive edema elevates tissue pressure above capillary pressure, thus ending arterial perfusion and initiating a cascade of events that results in compartment syndrome. The risk for this complication is increased when ischemia time is prolonged; in the presence of combined arterial and venous injury; after ligation or repair of a major artery or vein; or in the presence of significant soft tissue injury, frequently concomitant with a long bone fracture. After restoration of arterial flow to a previously ischemic limb, a cascade of reperfusion injury results from release of oxygen free radicals, lipid peroxidation, and influx of intracellular calcium.

These mediators give rise to progressive cellular damage, edema, and necrosis, thereby propagating the vicious cycle that increases compartment pressure. Consequently, frequent reexamination of the limb is indicated to assess compartment pressure after arterial repair or in the high-risk circumstances listed earlier. Compartment syndrome is discussed in more detail in Chapter 42.

CLINICAL FEATURES

Detection and treatment of vascular injuries takes place within the context of the overall resuscitation of the patient according to established principles of trauma care. If the source of bleeding is readily identifiable, it is compressed with digital pressure. Although control of active bleeding is being achieved in this manner, detection and treatment of other life-threatening injuries proceed concurrently. Peripheral vascular injury can occur coincident with other life-threatening trauma, which may take higher priority in resuscitation. In other cases, peripheral vascular injury may be the most serious or only injury, and evaluation and management of this type of injury can proceed directly. Many patients have no evidence of injury but are considered at risk for vascular injury because of penetrating wounds that traverse the course of major neurovascular bundles, or because they have sustained high-risk injuries, such as posterior knee dislocation. In addition, patients without acute trauma, but with symptoms of intermittent claudication, evidence of injury but are considered at risk for vascular injury because of penetrating wounds that traverse the course of major neurovascular bundles, or because they have sustained high-risk injuries, such as posterior knee dislocation. In addition, patients without acute trauma, but with symptoms of intermittent claudication, may have no evidence of injury but are considered at risk for vascular injury because of penetrating wounds that traverse the course of major neurovascular bundles, or because they have sustained high-risk injuries, such as posterior knee dislocation.

Peripheral vascular injury can be divided into three categories by physical examination: hard findings, soft findings, and asymptomatic high-risk wounds based on the mechanism of injury.

Hard Findings of Vascular Injury

Many patients have classic “hard” findings of arterial injury, listed in Table 41.1. The incidence of arterial injury in patients with any hard finding is consistently greater than 90%, and the presence of these findings requires further investigation by emergency angiography/computed tomography angiography (CTA) or, more commonly, immediate surgical intervention, depending on the duration of warm ischemia and the overall status of the patient.

Soft Findings of Vascular Injury

An additional group of patients have “soft” findings of vascular injury (see Table 41.1). Up to 35% of patients with “soft” findings of vascular injury have positive angiographic studies, although only a small proportion of these injuries require emergency repair.

The significance of prolonged capillary refill (>2 seconds) is controversial; some experts find it to be a reliable sign of vascular injury (when combined with a pulse deficit) and consider delayed

ABI, Ankle-brachial index.
capillary refill to be a valid “soft sign” of vascular injury. However, capillary refill is age, gender, and temperature dependent, and an arbitrary 2 second cutoff results in a significant false-positive rate, especially in older patients. Delayed capillary refill by itself is an unreliable predictor of arterial injury, but the presence of delayed capillary refill in conjunction with a proximate penetrating injury or the presence of one or more soft signs warrants, at the least, repeated hourly examination.

Isolated penetrating injury to a peripheral nerve is commonly associated with vascular injury because of the close proximity of these structures within the neurovascular bundles. Vascular injury occurs in up to half of cases of penetrating peripheral nerve injury, and vice versa. It can be difficult to distinguish whether pain, paresthesias, or paralysis are caused by a primary nerve injury, an associated vascular injury causing compression of the nerve, or compartment syndrome. In general, primary nerve injury occurs immediately at the time of injury, whereas vascular neuropathy occurs over minutes to hours after the injury.

**Asymptomatic High-Risk Wounds**

Major neurovascular bundles include large limb arteries proximal to critical branch points (Table 41.2). Proximity of a penetrating wound to a neurovascular bundle is defined variably as within 1 cm, 1 inch, or 5 cm. This concept is useful in evaluating patients with penetrating injury but without evidence of vascular injury. We consider penetrating wounds that occur within 1 cm of a major neurovascular bundle or whose presumed trajectory has crossed such a bundle to be sufficiently likely to produce an occult vascular injury that they warrant frequent (every 30 to 60 minutes) evaluation for the first 4 to 6 hours to ensure that a developing vascular injury is not missed within the warm ischemia window. Routine imaging is not, however, indicated based on proximity alone.

In addition, a small minority of patients with high-risk injuries, such as bites from large dogs or other animals, displaced fractures, crush injuries, or major joint dislocations (especially knee dislocation), may initially have occult vascular injuries that are not detected on physical examination. The risk of missing such injuries is that the traditional 6-hour window of warm ischemia time will be exceeded, or the patient will experience delayed complications resulting in limb loss. Patients with intimal flaps may be completely asymptomatic initially but subsequently develop arterial thrombosis. Similarly, pseudoaneurysms progressively enlarge to produce compression of adjacent structures but may be very small and undetectable on initial physical examination. Consequently, these patients also should undergo serial physical examinations.

Due to their noncompressible location, blunt subclavian injuries can be particularly challenging. These are often associated with clavicular fracture or dislocation (however, contrary to long-held belief, isolated first rib fracture is rarely combined with vascular injury unless posterior displacement occurs). Shear injury of the subclavian artery can occur as a result of a loose shoulder restraint during a motor vehicle collision (MVC). Interestingly, penetrating subclavian vein injuries are even more lethal than those to the artery, because in addition to massive blood loss, there is a relatively high risk of massive air embolism, which is frequently fatal.

Popliteal artery injuries can often be a result of knee dislocations, most of which will have spontaneously reduced. Patients showing complete ligamentous disruption of the knee on physical examination should be suspected of having a spontaneously reduced knee dislocation. Hemarthrosis may also be absent if the joint capsule is torn because blood can track into the fascial planes.

**History**

In patients who achieve and maintain hemodynamic stability, a more comprehensive history can be obtained. Important historical points to note include the exact time and mechanism of the injury. The time of injury is important because of the significant morbidity that results from prolonged warm ischemia time. The mechanism is of clinical and often forensic importance in that injuries are frequently inflicted during a criminal act or in the workplace. Various mechanisms of injury may mandate special reporting and may alter the patient’s ultimate disposition. Certain types of injuries, such as crush or bite wounds, are particularly prone to complications. The occupation, avocation, and hand dominance of the patient are pertinent to determine the best approach to achieve maximum functionality. Comorbid medical conditions may also be important. Patients who are immunocompromised because of diabetes, acquired immunodeficiency syndrome (AIDS), asplenia, cancer, or steroid use are at increased risk for infection and impaired wound healing. Patients with preexisting vascular insufficiency have more tenuous perfusion, are more susceptible to ischemia from elevated compartment pressure, and have a higher incidence of complications. As with most aspects of trauma care, patients whose sensorium is altered by head injury or intoxication, patients with spinal cord injury who cannot perceive pain, and those with significant painful distracting injuries will not reliably be able to report pain or paresthesias suggesting vascular insufficiency, so extra caution should be exercised in these cases.

Evidence of abdominal injury raises concern for injury to the iliac vessels, and virtually all iliac artery and vein injuries have associated trauma to the small or large intestine, bladder, solid viscer, or bony pelvis. The common and external iliac arteries are injured with equal frequency and more often than the internal iliac vessels. Approximately 80% of iliac vessel injuries are caused by penetrating trauma, and the remainder is mainly associated with pelvic fracture. Trauma to the iliac veins is responsible for massive bleeding in displaced pelvic fractures and often requires angiographic embolization.

**Physical Examination**

Despite advances in technology, meticulous physical examination in combination with comparison of blood pressures in the affected and unaffected limbs is the mainstay of diagnosis of vascular injury. Physical examination is directed at discovering evidence of local wound complications and distal ischemia suggestive of vascular injury. Pulses in the affected extremity are palpated to compare strength and quality between the injured limb and its uninjured counterpart. Isolated detection of a diminished pulse distal to the site of injury merits further evaluation rather than immediate surgery, because palpation of pulses is a relatively

inaccurate means of predicting arterial injury.\textsuperscript{12} False-positive findings of a pulse deficit may occur because of shock, in which all pulses are diminished; congenital absence of a pulse in one extremity; preexisting vascular disease; operator technique; or arterial spasm or compression. False-negative findings can occur with transmission of the pulse through a “soft clot,” past an intimal flap, or through collateral circulation. Distal pulses can persist despite significant arterial injury. Compression of an artery by casts, splints, or dressings may produce a pulseless extremity, and these should be removed if there is evidence of ischemia. Symptoms of limb ischemia may be apparent with absent radial and brachial pulses. However, pulses are completely absent in only a third of cases, because collateral flow from the thyrocervical trunk may provide sufficient perfusion to avoid the symptoms and signs of ischemia.\textsuperscript{1} Finally, although the pulse may be absent, the limb may be well perfused by collateral arterial supply, thus making immediate repair of the arterial injury less compelling. Comparative palpation of the injured and unaffected limbs can also detect differences in skin temperature that may suggest hypoperfusion. Testing two-point discrimination on the injured and unaffected limbs may help detect sensory deficits. Auscultation over the site of injury may reveal a bruit, which is present in more than half of patients with AVF. Repeat examination of any hematoma adjacent to a wound is indicated during the first 24 hours to determine whether it is expanding or pulsatile.

Despite the limitations just noted, reliance on the history and physical examination to triage patients to receive immediate surgery, imaging studies, or observation has been found to be relatively dependable, with a sensitivity and specificity for significant vascular injury both exceeding 90%.\textsuperscript{4} However, studies of military casualties suffering blast injury or high-velocity gunshot wounds have found physical examination to be less reliable than in studies of civilian casualties, likely because of the high energy nature of military wounds.

Neurologic deficits in the upper extremity occur in more than half of patients. The most severe of these injuries is damage to the brachial plexus, which occurs in nearly half of patients with blunt injury.

Differential Diagnoses

In many cases, peripheral vascular injury will be readily apparent by external bleeding or hematoma formation. In other cases, vascular injury is suspected by the location or nature of the trauma the patient sustained. In all patients, vascular injury is a clue to search for associated injuries, such as bony injuries, injuries to proximate nerves, and soft tissue injuries due to either direct trauma or compression secondary to compartment syndrome. Conversely, some cases of vascular injury may not be obvious on initial examination and should be sought when evaluating patients with potential deep vein thromboses, crush injuries, and other presentations of acute limb pain.

Diagnostic Testing

Plain Radiography

Plain radiographs of the affected extremity are indicated to detect fractures, joint penetration, and foreign bodies. With gunshot wounds, the sum of the number of intact bullets seen on radiographs and the number of entrance and exit wounds in the body should be an even number. Rarely, bullets or shotgun pellets can deflect off bone and travel sufficiently far as to not be visible on the radiograph. Bullets or pellets can migrate distally and produce vascular occlusion or migrate proximally through the venous system to the heart. When there is concern for a missing projectile, broaden the radiographic search.

Pulse Oximetry and Near-Infrared Spectroscopy

Pulse oximetry has been found to be a relative insensitive means of identifying limb ischemia after trauma. Clearly, in the absence of a pulse, no reading can be obtained. Beyond that, pulse oximetry should not be considered a discriminatory or useful test for vascular injury. Measurement of tissue oxygenation by near-infrared spectroscopy (NIRS) to quantify muscle oxyhemoglobin showed early promise as a possible noninvasive and simple means of detecting vascular injury; however, small clinical studies have found contradictory results in use of NIRS for this indication.\textsuperscript{3,4}

Handheld Doppler

Absent or diminished pulses in an injured extremity should be evaluated using a handheld Doppler. Arterial injury is suggested by absent Doppler signal, or by a change in the usual triphasic quality of the Doppler pulse to a biphasic or monophasic waveform, because the pulse is “damped” by partial occlusion.

Arterial Pressure Index and Ankle-Brachial Index

Measuring systolic blood pressure in the injured versus the uninjured extremity (arterial pressure index [API]) or measuring it in an injured leg at the ankle compared with brachial artery pressure (ankle-brachial index [ABI]) are both accurate means of screening for arterial injury. Systolic pressure is measured by inflating a standard blood pressure cuff proximal to the injury and recording handheld Doppler systolic pressure distal to the injury. The process is repeated on the uninjured limb (or the arm, if calculating an ABI), and a ratio of injured to uninjured systolic pressure is calculated. In general, a ratio less than 0.90 is considered abnormal and indicates need for further investigation. Clinical studies of API/ABI have shown promising results. In several studies, an API/ABI less than 0.90 yielded a sensitivity and specificity for the detection of vascular injury of over 95%, with correspondingly high positive and negative predictive values.\textsuperscript{15}

Patients with suspected vascular injury who have an API/ABI of 0.90 to 0.99 merit observation for 12 to 24 hours for repeated physical examination and API measurements to detect potentially evolving injury. Patients with normal physical examination findings and a completely normal (greater than or equal to 1.0) API/ABI can be safely discharged from the ED, provided that there are no other injuries requiring admission.

However, reliance on the API/ABI to screen for arterial injury is not always possible. Comparisons cannot be made when both limbs are injured or when severe soft tissue disruption precludes placement of a blood pressure tourniquet. Certain arteries (eg, the profunda femoris, profunda brachii, and peroneal arteries) normally do not produce palpable pulses, and so API/ABI is of limited usefulness if injuries to these vessels are suspected. Shotgun wounds often are associated with normal API/ABI measurements despite multiple small arterial wounds; catheter-based angiography is the preferred diagnostic modality in this group.

Despite the limitations previously noted, API/ABI has proved effective in screening patients with proximity wounds. The vast majority of injuries missed by API/ABI heal spontaneously. Those that do not heal generally present within 3 months with signs of arterial injury and can be repaired electively.

Ultrasound

Bedside B-mode (real-time) ultrasound, particularly with color flow Doppler (see later), can reliably identify loss of arterial pulsation in major vessels. However, B-mode ultrasound cannot visualize certain anatomic areas accurately (eg, subclavian and
angiography ranges from 83% to 100%, with a specificity of 99% to 100% and an accuracy of 96% to 100%.

Color flow Doppler converts Doppler echoes into quantitated visual signals. Flow toward the transducer is seen as red, and flow away from the transducer is seen as blue. The intensity of the color (the number of pixels on the screen) is proportional to flow through the vessel. Small prospective studies have indicated a high rate of accuracy in detecting arterial injury with color flow Doppler. Absence of flow is readily apparent, but subtle injuries, such as intimal flaps and small pseudoaneurysms, can be more difficult to identify than with CTA. The overall sensitivity of color flow Doppler in detecting arterial injury is 50% to 90%, with a specificity of 95% to 99%. The sensitivity for detecting injuries requiring surgical repair is greater than 90% (Figs. 41.6 and 41.7).

Computed Tomography and Magnetic Resonance Imaging

With a few important exceptions, CTA has largely replaced catheter-based angiography for the detection of peripheral
vascular injury in most trauma centers. Multi-detector helical computed tomography (CT) scanners have proven very accurate for diagnosis of peripheral vascular injury in multiple series with a sensitivity of 93% to 100% and specificity of 87% to 100% compared with catheter-based angiography. The advantages of CTA over catheter-based angiography are that it is noninvasive, readily available, and less costly and provides information on other injuries in the region being studied. However, there are several pitfalls to the use of CTA. Metallic artifact from bullets, orthopedic hardware, or other penetrating objects may obscure visualization of parts of a vessel, although with image reconstruction techniques, this problem can be largely overcome. Venous injuries may be missed depending on the phase of the contrast. The rapid image acquisition of current CT scanners makes timing of the contrast bolus more critical, and out-of-phase images may miss arterial injury. In practical terms, though, CTA is very useful in that it can be integrated into an overall plan for diagnostic imaging, including CT of the head and trunk, all of which can be accomplished rapidly. Because of the enhanced detail, accuracy, and speed of image acquisition with 64 and greater slice CT scanners and the ability to perform three-dimensional reconstructions, this modality has become the standard imaging technique for suspected vascular injury. Magnetic resonance angiography (MRA) has been described and accurately detects vascular injuries but has yet to prove clinically useful. MRI is also contraindicated in the presence of ferromagnetic foreign bodies.

**Arteriography**

Historically, catheter-based contrast angiography was used for diagnosing peripheral arterial injury. However, given the ready availability of CTA and additional steps necessary to obtain an angiography (transfer of the patient, activation of the angiography team, preparation of the angiography suite), CTA has replaced angiography as the initial diagnostic modality of choice in the ED. Even those patients who may need intervention (embolization of pseudoaneurysms, endovascular stent insertion to bypass a dissection or AVF, and injection of thrombolytic agents to dissolve thrombus are routinely performed via intra-arterial catheter) are best served by obtaining a rapidly available CTA to establish the diagnosis.

**Diagnosis of Specific Vascular Injuries**

Although the aforementioned diagnostic strategies apply to vascular trauma overall, certain injuries bear particular mention.

For subclavian artery injury, the combination of physical examination and chest x-ray findings suggestive of subclavian injury (hemоторax, pneumоторax, apical pleural cap, or wide mediastinum) identifies nearly all injuries, and arteriography is not indicated in the absence of findings. When injury is suspected and the patient is unstable, operative intervention is indicated. If the patient’s clinical condition permits, however, angiography can confirm the diagnosis and can locate the injury precisely. APs are not reliable with proximal thoracic outlet injuries because of collateral arterial flow. Ultrasound techniques are also relatively inaccurate in detecting subclavian injuries because of interference by overlying gas-filled lung tissue. Therefore in cases in which the clinical diagnosis is equivocal (soft signs of injury or proximity wounds), arteriography (CTA or catheter based) is required to detect the injury.

No consensus has been reached on the diagnostic approach to detect popliteal artery injury resulting from documented or suspected knee dislocation. It is, of course, unreasonable to perform routine arteriography on every case of obvious or suspected knee dislocation. Although the exact diagnostic strategy is institution specific and dependent on available resources, our hospital’s approach is to perform a CTA in cases of high-energy mechanisms of blunt trauma (eg, auto vs. pedestrian or MVC). For lower energy blunt mechanisms, such as athletic injury, we perform serial clinical evaluations, including ABI. However, patients with penetrating trauma and more than one hard sign of popliteal artery injury can be taken directly to the operating room for repair, because delaying these cases to obtain a CTA is unnecessary.

**MANAGEMENT**

Management of peripheral vascular injury is part of the total care of the trauma patient, including control of active hemorrhage by direct digital pressure. Blind clamping of a bleeding vessel is not recommended because of the risk of crushing adjacent nerves; however, clamping a clearly visible vessel can be effective. Tourniquet use for up to 6 hours is safe and effective, and it has been associated with increased survival in patients with major limb trauma. Tourniquets should be applied if direct pressure is insufficient to control bleeding and left in place until definitive surgical control can be achieved. Few complications are associated with the use of tourniquets, and almost all of these are transient. In cases in which proximal and distal control of large-vessel injuries cannot be readily achieved in the ED, insertion of a Foley catheter into the wound and inflation of the balloon with sterile water can temporarily tamponade the bleeding. Intravenous lines should not be started in the injured extremity, because they may be ineffective in delivering resuscitation fluid or medication and because extravasation from an injured vein may increase compartment pressure. Serial hemoglobin determinations may indicate unexpected blood loss from occult vascular injury. Patients with significant blood loss should have blood typed and crossmatched and may require immediate transfusion for stabilization. Patients with significant vascular injury often remain hypotensive despite such infusion and require further volume infusion or blood transfusion.

The issue of hypotensive resuscitation is controversial with regard to major vascular injuries. A tenuous clot can form in an injured artery and prevent further blood loss as long as the patient remains hypotensive. Once arterial pressure reaches a critical but variable point, the clot may be expelled and massive blood loss can ensue. Therefore, when an arterial injury is inaccessible for occlusion by direct pressure, the target blood pressure for resuscitation should be lowered to a systolic pressure of approximately 90 mm Hg. Overly rapid fluid administration in the field or in the ED can produce transient intravascular hypervolemia and may ultimately increase the rate of blood loss. Closely monitor vital signs and the total volume of fluid infused. Once a vascular injury has been identified, a specific diagnostic and therapeutic strategy should be developed that is consistent with the severity of the injury, the presence of other injuries, and the resources available. In hospitals without the ability to perform vascular repair, transfer to a trauma center should be initiated early. In cases in which the transfer will involve a delay of several hours, cooling the ischemic limb will avoid exceeding the critical 6-hour cutoff for warm ischemia. To accomplish this, wrap the limb in towels, and apply ice in plastic bags around the limb, avoiding direct contact of the ice to the limb, which can result in frostbite.

**Major Vascular Injuries**

Major vascular injuries that compromise the viability of a limb should be repaired within 6 hours to avoid irreversible ischemic neuropathy and myonecrosis. Treatment of vascular injury has changed dramatically in the past 10 years. Endovascular treatment with self-expanding stents is currently the preferred technique for...
repair of these injuries in stable patients, and the majority of arterial repairs in the United States are now done with this technique.

**Upper Extremity Arterial Injuries**

For brachial artery injuries, limb salvage rates have improved to nearly 100% owing to efficient out-of-hospital transport, improved surgical techniques, and shorter time to first antibiotic dose. Repair is indicated in all cases because the amputation rate is high with ligation.

Injuries to forearm vessels detected by arteriography or ultrasound do not need to be repaired unless there are signs of ischemia in the hand; “hard signs” of arterial injury, such as an expanding hematoma, pseudoaneurysm, or AVF; or injury to both radial and ulnar arteries. However, some authors recommend repairing all these injuries because of the risk of intermittent claudication or cold intolerance in patients who have one artery ligated. Certain patients are almost exclusively dependent on the ulnar arterial supply to the hand because of an underdeveloped deep palmar arch. Clearly, ulnar artery injuries should be repaired in these patients. Ultimately, the decision to repair an arterial injury is in the domain of the vascular surgeon. Compartment syndrome in the forearm is common after repair of proximal arteries and veins and may require fasciotomy.

**Lower Extremity Arterial Injuries**

In patients with severe injuries to the lower extremities, an initial “damage control” laparotomy with temporary vascular shunting of the iliac vessels is often necessary as resuscitation continues. Distal ischemic complications occur in approximately one-third of repaired iliac arteries, and subsequent amputations are required in up to 20%.

Femoral artery injuries should be repaired as simple ligation of the common femoral artery results in amputation of the lower extremity in 80% of cases.

Factors that place patients at higher risk of amputation include severe soft tissue injury of the extremity, the presence of multiple fractures, major venous repair, or delay in repair exceeding 6 hours of warm ischemia time. Because of the high incidence of compartment syndrome with lower leg injuries, fasciotomy is required in half of cases, and some centers routinely perform fasciotomy in all such cases.

**Late Complications of Arterial Injury**

Despite timely optimal repair of arterial injuries, approximately one in five patients experiences delayed complications requiring further surgical intervention, including delayed amputation. The most common of such complications is delayed thrombosis, which often occurs after many months as stenosis at the repair site progresses. Other complications include intermittent claudication, chronic pain or edema of the limb, and aneurysm formation in the graft.

**Venous Injuries**

Venous injuries may be primarily ligated if the patient’s condition makes them unable to tolerate prolongation of surgery. However, the current trend is to repair major venous injuries if possible, particularly in the lower extremity, because wound healing is improved and the incidence of compartment syndrome, venous thrombosis, pulmonary embolism, and chronic edema is decreased. Extensive venous collaterals in the upper extremity make surgical repair less compelling.

**Minor Vascular Injuries**

Increasingly, minor nonocclusive vascular injuries are being treated expectantly. Criteria for observation of vascular injuries include low-velocity missile wounds, intact distal circulation, absence of active hemorrhage, and minimal arterial wall disruption on angiography if performed. Angiographic or CTA findings meeting these criteria include intimal flaps extending less than 5 mm and pseudoaneurysms smaller than 5 mm in diameter. Follow-up of these injuries with repeat angiography or ultrasound reveals that approximately 85% resolve spontaneously. Patients meeting these criteria can be monitored as outpatients for 3 months, with repeat physical examination and ultrasound to detect delayed complications. Most intimal flaps heal spontaneously, and asymptomatic injuries that do not disrupt perfusion of the limb can be treated conservatively with early administration of antiplatelet agents, such as clopidogrel or aspirin. However, almost all pseudoaneurysms ultimately require repair and, once discovered, should be repaired electively rather than undergoing continued observation. Failure to detect and repair occult arterial injuries in children often results in severe differential limb growth. Thus, a more aggressive policy of repairing arterial injuries that causes a relatively minor decrease in blood flow to a child’s growing limb may be justified.

**Arterial Spasm**

Isolated arterial spasm usually reverses with conservative treatment (topical warm saline or topical nitroglycerin paste), but prolonged spasm may require infusion of vasodilators, such as nitroglycerin, calcium channel blockers, alpha-blockers, nitroprusside, specific prostaglandin inhibitors, or warm saline.

**Antibiotics**

Current guidelines call for empirical gram-positive and gram-negative antibiotic administration for all patients with peripheral vascular injuries associated with open fractures, as well as those with extensive soft tissue injury. Appropriate coverage might include a first-generation cephalosporin (eg, cefazolin 1 to 2 g intravenously preoperatively) and gentamicin 5 to 7 mg/kg intravenously every 24 hours during the perioperative period.

**DISPOSITION**

Patients with confirmed injury to major vessels, equivocal findings on diagnostic tests, or symptoms of limb ischemia should be admitted to the hospital or ED observation unit for further investigation or serial physical examinations. Frequent vascular and neurological checks will be necessary in these patients, so step-down or intensive care unit levels of care may be necessary. Consultation with a vascular surgeon is indicated as soon as vascular injury is strongly suspected or the need for emergency operative repair established. Patients who are unstable because of vascular or other injuries may undergo further investigation or exploration in the operating room. If the treating hospital is incapable of performing vascular surgery or appropriate investigations, transfer to a trauma center should be initiated. Obtaining angiograms for proximity wounds in centers that are incapable of acting on positive results is unwise, because this may delay definitive care beyond the safe limits of warm ischemia time.
### KEY CONCEPTS

- The overall condition of the patient determines the extent of emergency department (ED) evaluation and stabilization. Critically injured patients may require immediate surgery, which should not be delayed for confirmatory studies of obvious vascular injury.
- Arterial injury may be readily apparent or clinically occult. In patients with high-energy blunt mechanisms, computed tomography angiography (CTA) should be the initial diagnostic modality of choice. In patients with lower-energy mechanisms, serial physical examinations may be performed instead.
- Symptoms of arterial injury may be delayed by hours to months after the initial injury. Late onset of symptoms suggests delayed thrombosis, pseudoaneurysm or arteriovenous fistulae (AVF) formation, compartment syndrome, or intermittent claudication, resulting from stenosis or reliance on small-caliber collateral vessels for arterial perfusion.
- Compartment syndrome frequently develops in limbs with arterial injury, particularly injuries of the lower leg, and fasciotomy is often required.
- Many vascular injuries are amenable to endovascular treatment with self-expanding stents. This results in fewer complications, lower cost, and earlier discharge from the hospital.

A 45-year-old man complains of right leg pain and edema shortly after surgery for a mid-shaft femur fracture. Physical examination reveals decreased distal pulses in the extremity. What is the most important diagnosis to consider in this patient?

A. Anemia causing poor tissue oxygenation
B. Compartment syndrome
C. Intimal flap
D. Pseudoaneurysm
E. Vessel stricture Answer: B. Although individuals may vary, 6 hours of complete warm ischemia is generally considered the point at which irreversible nerve and muscle damage begins to occur. After 6 hours of warm ischemia, 10% of patients will have irreversible damage; by 12 hours, 90% will have irreversible damage. Artificially cooling the limb to just higher than freezing temperature will reduce the metabolic demands of ischemic tissues and greatly prolong the tissue’s tolerance of ischemia to 24 hours or more.

A 25-year-old man who sustained a gunshot wound to the right leg has an ankle-brachial index (ABI) of 0.9. What is the most appropriate next step in this patient’s management?

A. Admit for observation and repeat examinations.
B. Discharge the patient home with surgical follow-up.
C. Intimal flap
D. Pseudoaneurysm
E. Vessel stricture

After 6 hours of warm ischemia, 10% of patients will have irreversible damage; by 12 hours, 90% will have irreversible damage. Artificially cooling the limb to just higher than freezing temperature will reduce the metabolic demands of ischemic tissues and greatly prolong the tissue’s tolerance of ischemia to 24 hours or more.
C. Obtain an emergent computed tomography (CT) angiogram.
D. Obtain immediate vascular consultation.
E. Perform a Doppler ultrasound scan.

**Answer: A.** Patients with an ABI of 0.90 to 0.99 merit observation for 12 to 24 hours for repeat examinations and ABI measurements to detect evolving injury. In general, a ratio of less than 0.90 is considered abnormal and is an indication for further investigation, such as computed tomography angiography (CTA).

**41.5.** Which of the following is least likely to cause vascular injury to an extremity?
A. Close-range shotgun wound
B. Crush injury
C. Electrical injury
D. Gunshot wound from a long distance
E. Massive tissue avulsion

**Answer: D.** Close-range shotgun wounds can cause significant blunt trauma to vessels, as well as a higher rate of bone and nerve damage than gunshot wounds. An open avulsion injury to limb is particularly severe because the skin is the final structure to be disrupted, and there is inevitable injury to deeper vessels and nerves. Vascular injury must be suspected in patients with massive soft tissue avulsion or crush injury, displaced long bone fractures, and electrical or lightning injuries.
MANAGEMENT PRINCIPLES

Although only rarely life-threatening, orthopedic injuries may threaten a limb or its function, and accurate early diagnosis and treatment can avert long-term complications. Many of these injuries can and should be treated definitively by the emergency clinician. Consultation with an orthopedist should be sought for the treatment of most long bone fractures, open fractures, injuries with joint violation, and injuries with neurovascular compromise and for follow-up of certain patients initially treated in the emergency department (ED).

When evaluating a potential orthopedic injury, 10 basic general principles should be considered:

1. Most orthopedic injuries can be inferred by understanding the chief complaint, age of the patient, mechanism of injury, and estimate of the amount of energy delivered.
2. A careful history and physical examination can predict radiographic findings with a high degree of accuracy. A presumptive diagnosis before a radiographic study may prompt the emergency clinician to order special views necessary to diagnose an injury correctly. Many fractures were accurately described before the advent of roentgenology (Table 42.1).
3. If a fracture is suggested clinically, but radiographic films appear negative, the patient should initially be treated with immobilization as though a fracture were present. Similarly, certain soft tissue injuries require prompt identification and follow-up and should be immobilized despite normal radiographic findings.
4. There are criteria for adequate radiographic studies; inadequate studies should not be accepted.
5. In general, when a fracture is suspected, radiographic studies should be performed before most reductions are attempted, except when a delay could be potentially harmful to the patient or in some field situations, such as neurovascular compromise or ischemic skin.
6. Neurovascular competence should be assessed and recorded prior to and following all reductions and after application of immobilization.
7. Patients must be checked for the ability to ambulate safely before discharge from the ED and should not be discharged unless safe transportation can be established.
8. Patients should receive explicit aftercare instructions before leaving the ED, covering areas such as monitoring for signs of neurovascular compromise or increasing compartment pressure, cast care, weightbearing, crutch use, and an explicit plan and timing for follow-up.
9. In a patient with multiple trauma, noncritical orthopedic injuries should be diagnosed and treated only after more threatening injuries have been addressed.
10. All orthopedic injuries should be described precisely and according to established conventions. When communicating with an orthopedic consultant, this may affect decisions regarding disposition of a patient and operative versus nonoperative management.

FRACTURES

Fracture Nomenclature

Describing orthopedic injuries with precise language according to established convention enables accurate clear communication with other parties. Terms commonly used to describe a fracture are listed in Box 42.1. A fracture is a break in the continuity of bone. Clinically, a history of loss of function, pain, tenderness, swelling, abnormal motion, and deformity suggests a fracture. Radiographic studies are the mainstay of diagnosis and are usually, although not always, confirmatory. At times, use of special views, radionuclide bone scans, computed tomography (CT), and/or magnetic resonance imaging (MRI) is necessary to confirm a clinical impression. These studies should be considered when the clinical evidence is at odds with the findings of routine radiography, although are rarely required emergently.

General Descriptors

Description of a fracture should begin by stating whether the fracture is closed or open. In a closed fracture, the skin and soft tissue overlying the fracture site are intact. The fracture is considered open if it is, or has been, exposed to the outside environment in any manner, which may not be immediately obvious. Occasionally, it may be difficult to determine whether a small wound in proximity to a fracture actually communicates with that fracture. Although some emergency clinicians advocate probing such a wound with a blunt sterile swab to establish a relationship, no study has established the safety, benefit, or accuracy of this maneuver. If doubt exists, an open fracture should be assumed to be present.

The next item that should be noted in the description of a fracture is the exact anatomic location, including the name of the bone, left or right, and standard reference points along the bone (eg, the humeral neck or posterior tibial tubercle). Long bones can be divided into thirds—proximal, middle, or distal—and these thirds, or the junction of any two of them (eg, the junction of the middle and distal thirds of the tibia), are used to describe fractures. The most descriptive language possible should be used. It is better to say “closed fracture of the right ulnar styloid” than “closed fracture of the right distal ulna” because the former conveys more precise anatomic information.

<tr>
<th>FRACTURE EPONYM OR NAME</th>
<th>DESCRIPTION</th>
<th>COMMENT</th>
</tr>
</thead>
<tbody>
<tr>
<td>Aviator</td>
<td>Vertical fracture of the neck of the talus with subtalar dislocation and backward displacement of the body</td>
<td>First described in flyers during World War I; arises from forced dorsiflexion of the foot in flying accidents and in traffic accidents after a head-on collision</td>
</tr>
<tr>
<td>Barton</td>
<td>Intraarticular fracture-dislocation of the wrist</td>
<td>Considered complicated and unstable; requires surgical reduction in most cases; described by Barton in 1838 before the advent of radiography</td>
</tr>
<tr>
<td>Dorsal Barton</td>
<td>Oblique intraarticular fracture of the dorsal rim of the distal radius with displacement of the carpus along with the fracture fragment</td>
<td>Results from high-velocity impact across the articular surface of the radiocarpal joint, with the wrist in dorsiflexion at the moment of impact</td>
</tr>
<tr>
<td>Volar Barton</td>
<td>Wedge-shaped articular fragment sheared off the volar surface of the radius (volar rim fracture), displaced volarly along with the carpus</td>
<td>Similar mechanism as dorsal Barton but with wrist in volar flexion at time of injury; also referred to as reverse Barton’s fracture; much rarer than dorsal Barton fracture</td>
</tr>
<tr>
<td>Bennett</td>
<td>Oblique fracture through base of the first metacarpal, with dislocation of the radial portion of the articular surface</td>
<td>Usually produced by direct force applied to the end of the metacarpal; dorsal capsular structures disrupted by the dislocation; marked tenderness along medial base of thumb</td>
</tr>
<tr>
<td>Bosworth</td>
<td>Fracture-dislocation of the ankle resulting in the fibula being entrapped behind the tibia</td>
<td>Rare injury, produced by severe external rotation force applied to the foot; physical examination reveals foot severely externally rotated in relation to the tibia</td>
</tr>
<tr>
<td>Boxer</td>
<td>Fracture of the neck of the fourth or fifth metacarpal</td>
<td>Results from striking a clenched fist into an unyielding object, usually during an altercation, or against a wall, out of frustration or anger</td>
</tr>
<tr>
<td>Chance</td>
<td>Vertebral fracture, usually lumbar, involving the posterior spinous process, pedicles, and vertebral body</td>
<td>Caused by simultaneous flexion and distraction forces on the spinal column, usually associated with use of lap seat belts; anterior column fails in tension, along with the middle and posterior columns; may be misdiagnosed as a compression fracture</td>
</tr>
<tr>
<td>Chauffeur</td>
<td>Solitary fracture of radial styloid</td>
<td>Occurs from tension forces sustained during ulnar deviation and supination of the wrist; name derived from occurrence in chauffeurs who suffered violent, direct blows to the radius incurred while turning the crank on a car, only to have it snap back, during previous eras</td>
</tr>
<tr>
<td>Clay shoveler</td>
<td>Fracture of the tip of the spinous process of the sixth or seventh cervical vertebra</td>
<td>First described in Australian clay shovellers who sustained a fracture of the spinous process by traction as they lifted heavy loads of clay</td>
</tr>
<tr>
<td>Colles</td>
<td>Fracture of the distal radius with dorsal displacement and volar angulation, with or without an ulnar styloid fracture</td>
<td>Most common wrist fracture in adults, especially in older adults; results from fall on an outstretched hand; also known as silver fork deformity, which accurately describes the gross appearance in the lateral view; first described by Colles in 1814, before the advent of radiography</td>
</tr>
<tr>
<td>Cotton</td>
<td>Trimalleolar fracture</td>
<td>Fracture of the lateral malleolus, fracture of the posterior malleolus, and either a fracture of the medial malleolus or disruption of the deltoid ligament, with visible widening of the mortise on ankle radiograph</td>
</tr>
<tr>
<td>Dashboard fracture</td>
<td>Fracture of the posterior rim of the acetabulum</td>
<td>Named for mechanism of injury—a seated passenger striking the knee on a dashboard, driving the head of the femur into the acetabulum</td>
</tr>
<tr>
<td>Dupuytren</td>
<td>Fracture-dislocation of the ankle</td>
<td>Results from a similar mechanism as the better known Maisonneuve fracture (ie, external rotation of the ankle), resulting in deltoid ligament rupture or medial malleolus fracture, diastasis of the inferior tibiofibular joint, and indirect fracture of the fibular shaft; Maisonneuve was a student of Dupuytren</td>
</tr>
<tr>
<td>Essex-Lopresti</td>
<td>Fracture of radial head with dislocation of the distal radioulnar joint</td>
<td>Results from longitudinal (axial) compression of the forearm</td>
</tr>
<tr>
<td>Galeazzi</td>
<td>Fracture of the shaft of the radius with dislocation of the distal radioulnar joint; ligaments of inferior radioulnar joint ruptured, head of ulna displaced from ulnar notch of the radius</td>
<td>Results from fall on outstretched hand, with the wrist in extension and the forearm forcibly pronated; inherently unstable, with tendency to redisplace after reduction</td>
</tr>
<tr>
<td>Fracture Eponym or Name</td>
<td>Description</td>
<td>Comment</td>
</tr>
<tr>
<td>-------------------------</td>
<td>-------------</td>
<td>---------</td>
</tr>
<tr>
<td>Hangman Fracture</td>
<td>Fracture-dislocation of atlas and axis, specifically of pars interarticularis of C2 and disruption of C2-3 junction; separation occurs between second and third vertebral bodies from anterior to posterior side</td>
<td>Results from extreme hyperextension during abrupt deceleration; most common cause is the forehead striking the windshield of a car during a collision; a bit of a misnomer in that hanging usually produces death by strangulation rather than cord damage</td>
</tr>
<tr>
<td>Hume</td>
<td>Fracture of the proximal ulna associated with forward dislocation of the head of the radius</td>
<td>Essentially high Monteggia injury</td>
</tr>
<tr>
<td>Jefferson</td>
<td>Burst fracture of ring of C1, or atlas</td>
<td>Axial loading results in a shattering of the ring of the atlas; decompressive type of injury; associated with disruption of transverse ligament; unstable injury</td>
</tr>
<tr>
<td>Jones</td>
<td>Transverse fracture of the metatarsal base, occurring at least 15 mm distal to the proximal end of the bone, distal to the insertion of the peroneus brevis</td>
<td>Should not be confused with the more common avulsion fracture of fifth metatarsal styloid, produced by avulsion at the insertion of the peroneus brevis; Jones described the fracture that bears his name in 1902, after sustaining the injury himself while dancing.</td>
</tr>
<tr>
<td>Le Fort</td>
<td>Maxillary fracture</td>
<td>Types I, II, and III (see Chapter 42)</td>
</tr>
<tr>
<td>Le Fort-Wagstaffe</td>
<td>Avulsion fracture of the anterior cortex of the lateral malleolus</td>
<td>Rare pull-off injury of the fibular attachment of the anterior tibiofibular ligament</td>
</tr>
<tr>
<td>Lisfranc</td>
<td>Fracture located around the tarsometatarsal (Lisfranc) joint, usually associated with dislocation of this joint</td>
<td>Lisfranc, a field surgeon in Napoleon’s army, described an amputation performed through the tarsometatarsal joint in a soldier who caught his foot in a stirrup when he fell off his horse; since then, the joint has borne his name.</td>
</tr>
<tr>
<td>Maisonneuve</td>
<td>Fracture of proximal third of fibula associated with rupture of the deltoid ligament or fracture of the medial malleolus and disruption of the syndesmosis</td>
<td>Results from external rotation of the ankle with transmission of forces through syndesmosis; proximally, the force is relieved by fracture of the fibula; described experimentally in 1840, before radiography</td>
</tr>
<tr>
<td>Malgaigne</td>
<td>Fracture of the ilium near the sacroiliac joint with displacement of the symphysis, or a dislocation of the sacroiliac joint with fracture of both ipsilateral pubic rami</td>
<td>Resultant pelvic injury is unstable; described by Malgaigne, based on clinical findings, in 1847</td>
</tr>
<tr>
<td>March</td>
<td>Fatigue, or stress, fracture of the metatarsal</td>
<td>Arises from long marches or other repetitive use trauma (e.g., marathon running) or, less commonly, from single stumbling movements</td>
</tr>
<tr>
<td>Monteggia</td>
<td>Fracture of the junction of the proximal and middle thirds of the ulna associated with anterior dislocation of the radial head.</td>
<td>Usually caused by fall on outstretched hand along with forced pronation of forearm or by a direct blow on the posterior aspect of the ulna; reported by Monteggia in 1814</td>
</tr>
<tr>
<td>Nightstick</td>
<td>Fracture of ulna, radius, or both</td>
<td>Name derived from a citizen’s attempt to protect himself from a police officer’s baton or “nightstick” by offering the forearm</td>
</tr>
<tr>
<td>Piedmont</td>
<td>Closed fracture of the radius at the middle third–distal third junction, without associated ulnar fracture</td>
<td>Named for a series of cases presented at the Piedmont Orthopaedic Society of Durham, North Carolina</td>
</tr>
<tr>
<td>Pott</td>
<td>Definitions vary (see comment); usually a bimalleolar fracture or fracture of the distal fibula, 4–7 cm above the lateral malleolus</td>
<td>The exact fracture Pott described in 1769 is uncertain; clearly, it referred to a fracture of the lower fibula, usually associated with other fractures or dislocations about the ankle.</td>
</tr>
<tr>
<td>Rolando</td>
<td>Intraarticular fracture at base of metacarpal; frequently Y- or T-shaped, or may be severely comminuted</td>
<td>Produced by an axial load with the metacarpal in partial flexion; worse prognosis than a Bennett fracture and, fortunately, rarer</td>
</tr>
<tr>
<td>Salter-Harris</td>
<td>Epiphyseal fracture occurring in children or adolescents</td>
<td>Graded I–V, depending on degree of involvement and/or displacement of epiphysis and metaphysis (see text dealing with Salter-Harris fractures and Table 42.2)</td>
</tr>
<tr>
<td>Smith</td>
<td>Extraarticular fracture of the distal radius with volar displacement of distal fragment</td>
<td>Reverse of the Colles fracture but much more uncommon; sometimes referred to as a garden spade deformity; usually results from fall with force to back of hand; first described by Smith in 1847</td>
</tr>
<tr>
<td>Stener</td>
<td>Avulsion of the ulnar corner of the base of the proximal phalanx of the thumb</td>
<td>Bony equivalent of rupture of the ulnar collateral ligament, or so-called gamekeeper’s thumb</td>
</tr>

### Box 42.1
Fracture Description

**Identification**
- Open versus closed
- Exact anatomic location
- Direction of fracture line
- Simple, comminuted
- Position (displacement, alignment)

**Additional Modifiers**
- Complete versus incomplete
- Involvement of articular surface (%)
- Avulsion
- Impaction
  - Depression
  - Compression

**Special Situations**
- Pathologic
- Stress

An additional modifier describes the direction of the fracture line in relation to the long axis of the bone in question. A transverse fracture occurs at a right angle to the long axis of the bone (Fig. 42.1A), whereas an oblique fracture runs oblique to the long axis of the bone (see Fig. 42.1B). A spiral fracture results from a rotational force and encircles the shaft of a long bone in a spiral fashion (see Fig. 42.1C). A fracture with more than two fragments is termed comminuted (see Fig. 42.1D).

The position and alignment of the fracture fragments (ie, their relationship to one another) should be described. Fragments are described relative to their normal position, and any deviation from normal is termed displacement. By convention, the position of the distal fragment is described relative to the proximal one. Displacement may be described as a quantitative measurement (ie, in millimeters) or as a percentage of the bone width. Fig. 42.2 shows a dorsal displacement of the fractured radius, and Fig. 42.3 shows lateral, or valgus, displacement of the distal tibia and fibula.

The terms valgus and varus are sometimes confusing. The term alignment refers to the relationship of the longitudinal axis of one fragment to another; deviation from the normal alignment is...
termed \textit{angulation}. The direction of angulation is determined by the direction of the apex of an angle formed by the two fracture fragments (Fig. 42.4). The term \textit{valgus} denotes a deformity in which the apex of the deformity points towards the midline. Conversely, the term \textit{varus} denotes a deformity in which the apex of the angulation points away from the midline. The relative position or angulation of the distal fragment of a fracture may also be described with terms such as \textit{radial} or \textit{ulnar}, \textit{dorsal} or \textit{volar}, \textit{anterior} or \textit{posterior}, and \textit{lateral} or \textit{medial}. One should also be aware of rotational deformity, present when the distal fragment of a fracture is rotated to some degree along the axis of the bone itself. Especially in the digits of the hand, clinically apparent radial or ulnar deviation of a flexed finger can occur, and radiographs often underestimate the degree of clinical deformity and rotation present.

\textbf{Descriptive Modifiers}

A fracture is termed \textit{complete} if it interrupts both cortices of the bone on orthogonal radiographic views and termed \textit{incomplete} if one cortex remains intact. It should be noted whether a fracture extends into and involves an articular surface. Frequently, the percentage of articular surface involved can only be estimated; in some cases the percentage that is actually involved dictates the need to perform a surgical reduction. In general, it is important that the articular surface be restored to anatomic integrity to prevent consequent posttraumatic arthropathy.

The term \textit{avulsion fracture} refers to a bone fragment that is pulled away from its normal position by the forceful contraction of a muscle (Fig. 42.5A) or the resistance of a tendon or ligament to a force in the opposite direction (see Fig. 42.5B). The term \textit{impaction} refers to the forceful collapse of one fragment of bone into or onto another. In the proximal humerus, this collapse typically occurs in a telescoping manner, particularly in older patients, whose bones are soft and brittle. In the tibial plateau, impaction occurs frequently in the form of a depression (Fig. 42.6A and B) and, in the vertebral bodies, impaction frequently occurs in the form of compression (see Fig. 42.6C).

A fracture that occurs through abnormal or diseased bone is termed \textit{pathologic}. A pathologic fracture is suggested whenever a fracture occurs from seemingly trivial trauma. Diseases that cause structural weakness predisposing to injury include primary or metastatic malignancies, bone cysts, enchondromata, and giant cell tumors. In addition, metabolic diseases such as osteomalacia, scurvy, rickets, and Paget’s disease all alter bone density, which makes them susceptible to fracture. The term \textit{pathologic} is also often applied to fractures through osteopenic bone when the demineralization is a result of disuse, as in polio. In contrast, fractures through osteoporotic bone of older adults usually are not described as pathologic; these are referred to as geriatric or insufficiency fractures.

When fractures occur in normal bones and a history of so-called trivial trauma is elicited, violence or battering should be suspected. Repeated low-intensity forces may lead to resorption of normal bone, resulting in a stress fracture. Other terms for this condition are \textit{fatigue fracture} and \textit{march fracture} (see Table 42.1). Most stress fractures occur in the lower extremities and affect individuals involved in activities such as running, basketball, aerobics, and dancing. There is often a history of functional pain leading up to the fracture. Extrinsic factors such as training regimens, type of equipment used, and nutrition habits, as well as intrinsic factors such as anatomic variation, muscle endurance, and hormonal factors, have all been associated with stress fractures. These injuries may not be recognizable on initial plain films; therefore, management should be based on the clinical diagnosis. The tibia, fibula, metatarsals, navicular, cuneiform, calcaneus, femoral neck, or femoral shaft may be involved.

\textbf{Fracture Eponyms}

Many fractures were described before the advent of radiography and are described by an eponym rather than the exact bony injury.
Fig. 42.5. Avulsion fractures. A, Musculotendinous avulsions of small bone fragments from the head of the humerus (arrows). B, Extensor tendon avulsion of bone from the base of the middle phalanx (arrow).

Fig. 42.6. A, B, Tibial plateau fracture. C, Vertebral body compression fracture (arrows).
These eponyms reflect the rich history of orthopedic care and, despite the objections of some, are still commonly used to describe orthopedic injuries (see Table 42.1).

Fracture Healing

The goal of fracture reduction is to realign bony fragments so that healing or union can take place, and normal function is restored. Rupture of vessels crossing the fracture line forms a hematoma, which eventually resorbs and provides the first continuity between the fragments. This procallus provides no structural rigidity for bearing stress but, with remodeling, callus is subsequently formed on the periosteal and endosteal surfaces of the bone, acting as a biologic splint. The callus completely ossifies and, over several months to 1 year, remodels and becomes indistinguishable from mature bone.

Radiographic studies conducted 10 to 14 days after injury show the bone surrounding the fracture line becoming more visible because of localized bone resorption and hyperemia during the inflammatory phase. After 2 to 4 weeks, soft tissue swelling has regressed, and callus first becomes visible, initially in a mottled pattern and then taking on a dense appearance. The callus undergoes organization, with peripheral margins becoming smooth as physically unstrained portions are resorbed.

In a healthy adult, the whole process from injury to consolidation takes about 2 months for the humerus and about 4 months for a large bone such as the femur. Oblique fractures tend to heal more quickly than transverse fractures. The rate of fracture healing is affected by many factors, including the type of bone (cancellous bone heals faster than cortical bone), degree of fracture and opposition, and systemic states, such as hyperthyroidism or illness requiring ongoing corticosteroid treatment. Appropriately timed weightbearing can increase the rate of ossification of callus, whereas premature or excessive weightbearing can create a nonunion.

On a radiograph, the presence of abundant bridging callus that is beginning to organize is usually associated with clinical union. If there is any suggestion of movement at the fracture site noted on clinical examination, union is regarded as inadequate. Several terms are used to denote abnormal healing. Delayed union is union that takes longer than usual for a particular fracture location; malunion occurs when a residual deformity exists; and nonunion is the failure of a fracture to unite. When nonunion results in a false joint, it is termed a pseudarthrosis.

If there is clinical evidence of stability, such as pain-free weightbearing, and radiographs demonstrate bridging bone on at least three cortices, a patient may resume activities of daily living with the injured extremity, even if the original fracture remains visible. The final process of complete radiographic consolidation can take several months.

Nomenclature and features of fractures in children are discussed in Chapter 175.

Diagnostic Modalities for Fractures

Plain Radiography

Conventional radiography is the mainstay for diagnosing fractures. In addition to confirming or excluding fractures, it can identify other pathologic conditions. With penetrating trauma, foreign bodies, air, and gas also may be detected.

Biplanar radiographs of an injured extremity should be obtained to delineate the bony injury fully. Conventional radiographic evaluation of long bones includes at least two orthogonal views, and an oblique view is also obtained if an injury adjacent to the joint is suspected. In certain locations, such as the phalanges, oblique views are necessary. If fracture is suspected despite negative radiographs, additional oblique views should be obtained. A fracture line is most visible when it is parallel to the x-ray beam and is invisible when it is exactly 90 degrees to the beam. To identify the extent of the fracture accurately, the entire bone should be visible on the image.

Each image is examined to ensure that proper technique has been used, and that no important area is omitted from the image. Overexposed images may fail to reveal an abnormality. Although some fine detail is lost on portable images, these are acceptable if the patient is unstable. Even with good technique, some fractures are not visible initially and do not appear until the margins of the fracture absorb. Absorption widens the radiolucent line, and a defect appears in 10 to 14 days. At that time, new bone produced beneath the periosteum at the margins of the fracture accentuates the fracture. Accordingly, if a fracture is suggested but is not visible at the initial visit, the injury should be treated as a fracture, reexamined clinically and radiographically in 10 to 14 days, and the patient should be informed of the rationale for this regimen.

Stress views of joints are occasionally used to evaluate the degree of ligamentous injury when other methods are not available. The value of stress views is limited because pain may not allow sufficient stress to be applied, and there is a possibility of injuring an already traumatized structure further.

Comparison views with the contralateral bone may be useful in selected situations but should not routinely be obtained in pediatric examinations (see Chapter 175). It is reasonable to use comparison views in cases in which radiographs are inconclusive and when confusion arises specifically out of the need to distinguish between a possible fracture and normal developmental anatomy. Comparison views sometimes are helpful in adults when there is a question regarding the presence of accessory ossicles or nonfused bones (eg, bipartite patella), because these anomalies are usually bilateral. The bleeding that inevitably accompanies fractures may produce soft tissue swelling, which may impinge on or obliterate overlying muscle planes. Fat pads, such as in the elbow, may be displaced. Another useful sign is the fat-fluid level, which may accompany fractures extending into the knee joint. The fat-fluid level is visible, however, only if the cross-table technique is used.

The bones themselves should be examined systematically. Normal adult bones possess a smooth contour. A distinct angle is highly suggestive of a fracture. In an adult, a lucent line that interrupts the smooth contour and usually extends to the opposite side represents a typical fracture. Nutrient arteries may be confused with fractures but have different radiographic characteristics: they are fine, sharply margined, and extend obliquely through the cortex and are less radiolucent than fractures. In addition, they do not extend to the opposite side of the bone. Pseudofractures can be created by soft tissue folds, bandages, or other overlying material or by a radiographic artifact called the Mach effect, which occurs at the margin of areas of differing density. If lucencies extend beyond the bones, the line is highly unlikely to represent a fracture.

Anomalous bones and calcified soft tissue likewise may be mistaken for fractures. Avulsions and small fracture fragments have an irregular surface that lacks well-corticated margins, and a defect in the adjacent bone is present, whereas anomalous ossification centers (accessory ossicles) and sesamoids are characterized by smooth cortical margins. Reference texts are useful in identifying and confirming these anomalies because they tend to occur in predictable locations. Compression fractures are represented by increased density rather than by a luency. Finally, the most commonly missed fracture is the second fracture. One should be diligent in searching for additional fractures after discovering the first fracture on a study. In particular, certain paired fractures, such as the distal tibia and proximal fibula, should be sought out.
Special Imaging Techniques

Computed Tomography. Although conventional radiography remains the initial imaging study of choice for skeletal trauma, CT offers a more detailed and diagnostically sensitive evaluation of bones and joints. Two-dimensional multiplanar reconstruction in any chosen plane, and three-dimensional surface rendering techniques provide images with unprecedented quality, even in the presence of metallic implants or fixation devices.

CT is used to confirm possible fractures or to define displacement, alignment, or fragmentation of fractures better. It is also useful in trauma to rule out a cervical spine fracture when plain films are equivocal and in noncompressive vertebral fractures to assess the number of fragments and their spatial relationship to the spinal canal. CT is used frequently to define the integrity of articular surfaces in the acetabulum, knee, wrist, or ankle and in Salter-Harris type IV fractures. In the multiple trauma patient requiring thoracic, abdominal, and pelvic CT imaging to rule out visceral injury, the soft tissue protocols may be adapted to acquire diagnostic bone images as well (Table 42.2). During imaging of the chest, abdomen, or pelvis, data sets are created from which the thoracolumbar spine and bony pelvis can be derived.

Magnetic Resonance Imaging. MRI constitutes the most advanced noninvasive examination of orthopedic structures, delineating lesions of bone, cartilage, ligaments, and other structures, such as menisci, disks, and epiphyseal structures. MRI is expensive and time-consuming and should be reserved for cases in which the diagnosis is in doubt, and specific findings would alter the treatment urgently.

Ultrasound Imaging. Point of care ultrasound is an effective tool for the diagnosis of fractures when conventional radiography is unavailable. Through the use of point of care ultrasonography, fractures are visualized as an interruption of the linear bony cortex and may be clinically correlated during the physical examination of the affected area. Ultrasound can be effective in the diagnosis of long bone fractures, orbital floor fractures, rib fractures, and occult fractures of the foot and ankle. Real-time ultrasound can be used during fracture reduction to confirm proper reduction and alignment of bony fragments.

Complications of Fractures

Infection (Osteomyelitis)

Any fracture communicating with the surface of the skin is termed an open fracture. Open fractures are treated as true, time-dependent orthopedic emergencies because of the risk of infection. The high morbidity associated with osteomyelitis dictates that therapy be initiated expeditiously, including parenteral administration of antibiotics as early as possible, emergent washout of debris, and coverage with a moist dressing. The Gustilo-Anderson classification is used to describe the various types of open fractures (Box 42.2).

Currently, suggested therapy includes a first-generation cephalosporin, such as cefazolin, 1 to 2 g IV tid, for all open fractures, with the addition of an aminoglycoside, such as gentamicin, 1 to 1.7 mg/kg IV tid, for type II or III fractures. With farm injuries or other scenarios that predispose to the development of anaerobic infection, such as clostridial myonecrosis (gas gangrene), ampicillin or penicillin should be added to the antibiotic regimen. Early versus delayed débridement of open fractures and its subsequent effect on rates of infection has been a source of debate. Historic guidelines recommending débridement of open fracture wounds within 6 hours of injury were based on animal experiments conducted in the 1890s. The timing of débridement—less than 6 hours versus more than 6 hours after injury—has not been proven to improve outcome, but general practice is to undertake débridement and irrigation of the wound within the first 24 hours of injury. Regardless, the goals of open fracture management should focus on early administration of antibiotics, tetanus prophylaxis, coverage of the wound, and splinting of the extremity.

BOX 42.2

Classification and Emergency Management of Open Fractures

**GRADES**

Grade I: Wound less than 1 cm long, punctured from below
Grade II: Laceration 5 cm long; no contamination or crush; no excessive soft tissue loss, flaps, or avulsion
Grade III: Large laceration, associated contamination or crush; frequently includes a segmental fracture
   IIIA: Involves extensive soft tissue stripping of bone
   IIIB: Periosteal stripping has occurred
   IIC: Major vascular injury present

**MANAGEMENT**

1. Control hemorrhage in field with sterile pressure dressing after carefully removing gross debris (eg, wood, clothing, leaves).
2. Splint without reduction, unless vascular compromise is present.
3. Irrigate with saline, cover with saline-soaked sponges after arrival in the emergency department.
4. Begin IV antibiotic prophylaxis, usually a first-generation cephalosporin for grade I, with the addition of an aminoglycoside for grades II and III.
5. Administration of tetanus prophylaxis, including tetanus immune globulin, for large crush wounds.
Certain open fractures of the finger and toes present a notable exception to the previous recommendation. Such injuries, especially an open distal tuft fracture, are common when the phalanx of a finger or toe is subject to crush injury (eg, by a door) and there is a skin defect overlying a fractured bone. There is no evidence that antibiotic use reduces the infection rate for these fractures, which rarely, if ever, develop osteomyelitis. Vigorous irrigation and débridement are adequate primary treatment for open phalangeal fractures in fingers and toes with intact digital arteries and can be provided by the emergency clinician without consultation.

**Hemorrhage**

Because of the rich blood supply to the skeleton, fractures can result in large amounts of blood loss, shock, and death from exsanguination. In particular, certain pelvic fractures can cause great blood loss because adequate tamponade is not possible. In adults, blood loss can range from 100 mL from a forearm fracture to 3 L from a pelvic fracture (Table 42.3). Such hemorrhage can be controlled in part by early stabilization of the injured area through splinting, a binder, or skeletal traction.

**Vascular Injuries**

Vascular injuries characteristically are associated with certain fractures and may be limb-threatening. Fractures and dislocations (at the femorotibial articulation) of the knee result from tremendous force, which often injures the popliteal artery. Fracture of the femoral neck requires emergent reduction and fixation to protect the blood supply to the femoral head. In the extremities, assessment of vascular injuries may be difficult. The initial survey should note the presence or absence of pulses and state of capillary filling. If an end artery is completely disrupted, the tissue distal to the injury may exhibit the classic five Ps: pain, pallor, pulselessness, paresthesias, and paralysis. Incomplete and subclinical injuries occasionally occur that initially may be asymptomatic and undetectable. Likewise, in an unconscious, multiply injured patient, major vascular injuries may not be obvious. The mechanism of injury and anatomy dictate the need to assess the possibility of an injured vessel. If pulses cannot be palpated, a Doppler stethoscope should be used to listen for blood flow. Even palpable pulses may be misleading because pulses may be normal in 10% to 20% of patients with significant arterial injuries. When pulses are present but the mechanism of injury suggests the possibility of vascular injury, additional diagnostic studies or surgical exploration may be necessary. If a limb is clearly not perfused, operative vascular exploration and repair should take place promptly. Late complications of undiagnosed vascular injuries include thrombosis, arteriovenous fistulae, aneurysm, false aneurysm, and tissue ischemia with limb dysfunction. Delay of vascular injury repair is a risk factor for consequent amputation. The evaluation of peripheral vascular injuries is discussed in Chapter 41.

| **TABLE 42.3** |
| Blood Loss Associated with Fracture in Adults |
| **FRACTURE SITE** | **AMOUNT OF BLOOD LOSS (mL)** |
| Radius and ulna | 150–250 |
| Humerus | 250 |
| Tibia and fibula | 500 |
| Femur | 1000 |
| Pelvis | 1500–3000 |

**Nerve Injuries**

Nerves can be injured by blunt or penetrating trauma:
- Neuapraxis is the contusion or traction injury of an otherwise intact nerve, with disruption of the ability to transmit impulses. Paralysis, if present, is transient, and sensory loss is slight. Normal function usually returns to a neurapraxic nerve in weeks to months.
- In axonotmesis, crush or traction result in more severe injury to axons within an intact epineurium. Because the Schwann tubes remain in continuity, spontaneous healing is possible but slow.
- Neurotmesis is the severing of a nerve, usually requiring surgical repair.

Age, site, injured nerve, and delay between injury and repair have all been shown to influence prognosis after microsurgical repair. Because of proximity, specific nerve injuries characteristically accompany certain fractures (Table 42.4). For example, in the upper extremity, a distal radius fracture caused by a high-energy insult can be associated with acute dysfunction of the median nerve. Deteriorating neurologic function may necessitate temporary or definitive stabilization of a fracture.

When the nerve is completely severed, all functions are absent, including the following: superficial sensation to touch, pain, and temperature; deep sensation to muscle and joint movements, position, deep pressure, and vibration; motor supply and deep tendon reflexes (to distally innervated muscle groups); and response to electrical stimulation. For less severe injuries, any subjective change in sensation should be noted. Light touch is a good screening test. Two-point discrimination is a more sensitive examination and should be used routinely in evaluating digital nerves. The discrimination on the injured digit is then compared with the uninjured ones. A normal two-point discrimination value at the fingertip of an adult is 4 mm, or discrimination may be compared to a noninjured digit. Evaluation of the innervation of the hand is discussed in Chapter 43.

**Compartment Syndrome**

Compartment syndrome is a serious, acute, emergency complication that should be considered whenever significant pain and paresthesias occur in an extremity after a fracture within an enclosed osseofascial space (Table 42.5). The immediate threat is to the viability of nerve and muscle tissue within the involved compartment, but infection, gangrene, myoglobinuria, and renal failure also may ensue if the diagnosis is not made in timely fashion. Compartment syndrome is usually associated with a

| **TABLE 42.4** |

| Hip dislocation | Femoral nerve |
| Femoral shaft fracture | Peroneal nerve |
| Knee dislocation | Tibial or peroneal nerve |
| Lateral tibial plateau fracture | Peroneal nerve |
closed long bone fracture of the tibia, but it also is well described in the thigh, forearm, arm, hand, and foot. In addition, compartment syndrome can occur with soft tissue trauma alone and even with open fractures. It also has been described in a host of unusual situations, including prolonged procedures in the lithotomy position, the tuck position (knees tucked to the chest for lumbar surgery), coma, spontaneous hemorrhage, extravasation of IV injections, and application of excessive traction in treatment of a fracture.

**Pathophysiology.** Increased pressure in a closed nonexpandable compartment essentially represents a mismatch between the volume of that space and its contents. As such, it may arise from one of three circumstances: (1) increased compartment contents; (2) decreased compartment volume; or (3) external pressure (Box 42.3). As tissue pressure increases, so does venous pressure, resulting in compromise of the local circulation and tissue hypoxia; this is believed to occur at pressures that are above normal diastolic pressure but below systemic arterial pressure because of a reduced arteriovenous gradient at the tissue level. The body responds by releasing histamine in an attempt to dilate capillaries and increase blood flow to the affected area. Histamine also increases capillary membrane permeability, resulting in a leak of proteins and fluid into the surrounding tissue and further increasing compartment pressure.

As tissue pressure continues to increase, venous blood flow is impaired as capillary perfusion pressure is exceeded. Finally, arterial capillary blood flow falls to a point at which the basic metabolic needs are no longer met, leading to ischemic necrosis of muscles and nerves within the compartment. An important concept in the management of compartment syndrome is that because local venous pressure cannot be significantly below local tissue pressure, and because elevation of a dependent limb decreases local arterial pressure by 0.8 mm Hg for each 1 cm of limb elevation, elevation of a limb with resultant reduction in the local arteriovenous gradient may be counterproductive and may exacerbate compartment syndrome. Vascular spasm seems to play an insignificant or minimal role in the development of compartment syndrome, as evidenced angiographically, where spasm has never been shown, and clinically, where it has been observed that distal pulses usually are maintained until late in the course.

Normal compartment pressure is 0 mm Hg. Microcirculation generally is impaired when tissue pressures reach 30 mm Hg or more; however, some patients can tolerate much higher compartment pressures without the development of compartment syndrome. Controversy exists over attempts to define compartment syndromes on the basis of specific tissue pressure. The tolerance to tissue ischemia varies among individuals because of shock, preexisting vascular disease, and other unknown factors. Inadequate perfusion and relative ischemia begin when tissue pressure within a closed compartment increases to within 20 mm Hg of a patient’s diastolic pressure or, more accurately, within 30 mm Hg of the mean arterial pressure. When tissue pressure equals or exceeds the patient’s diastolic blood pressure, tissue perfusion effectively ceases. The development of muscle ischemia depends not only on the magnitude but also on the duration of elevated pressure. Intracompartmental pressures do not measure muscle pressures directly, but they are directly related to the pressures that occur in the microcirculation.

**Causes of Compartment Syndrome**

### INCREASED COMPARTMENT CONTENT
- Bleeding
  - Major vascular injury
  - Coagulation disorder
  - Anticoagulant therapy
- Increased capillary filtration
  - Reperfusion after ischemia
    - Arterial bypass grafting
    - Embolectomy
    - Ergotamine ingestion
    - Cardiac catheterization
    - Lying on limb
- Trauma
  - Fracture
  - Convulsion
- Intensive use of muscle
  - Exercise
  - Seizures
  - Eclampsia
  - Tetany
- Burns
  - Thermal
  - Electrical
- Intravenous drug injection
- Orthopedic surgery
  - Tibial osteotomy
  - Hauser’s procedure
  - Reduction and internal fixation of fractures
- Snakebite
- Increased capillary filtration
- Intensive use of muscle
- Venous obstruction
  - Phlegmasia cerulea dolens (ie, acute inflammation and edema of the legs)
  - Ill-fitting leg brace
  - Venous ligation
- Diminished serum osmolarity (ie, nephrotic syndrome)

### DECREASED COMPARTMENT VOLUME
- Closure of fascial defects
- Excessive traction on fractured limbs

### MISCELLANEOUS
- Infiltrated infusion
- Pressure transfusion
- Leaky dialysis cannula
- Muscle hypertrophy
- Popliteal cyst

### EXTERNAL PRESSURE
- Tight casts, dressings, or air splints
- Lying on limb

The need for increasing amounts of analgesics should not lead to the conclusion that the analgesics are required because the pain is deep, burning, and unrelenting and is difficult to localize. The finding in compartment syndrome. Pain often is characterized as disproportionate to the injury or physical findings is a hallmark of compartment syndrome. In a conscious and fully oriented patient, pain that is present on passive stretching of the muscle groups in the suggested compartment is an important finding. In addition, active flexion of involved muscles may produce pain. Other reliable suggestive signs and symptoms are hypoesthesias and paresthesias in the distribution of nerves crossing the compartment or tenderness, tenseness, or sensation of tightness of the compartment.

**Anatomic Considerations and Risk Factors.** Compartment syndrome theoretically can develop in any location where neuromuscular tissue is contained in a limiting envelope. The condition has been reported in the leg, thigh, buttock, arm, forearm, and hand (Box 42.4). By virtue of its location and higher likelihood of sustaining high-energy trauma, the leg, particularly the anterior compartment, is most commonly involved. Higher rates of compartment syndrome are seen with open fractures than with closed fractures, despite the fascial rents that accompany open fractures. The higher energy of injury observed with open fractures, with resultant tissue trauma, swelling, and bleeding, may account for this observation.

Most patients with compartment syndrome have an associated long bone fracture, and fractures of the tibial shaft are particularly likely to cause increased compartment pressure. Up to one-third of patients, however, have only soft tissue injury without fracture. Compartment syndrome is more likely when there is a bleeding disorder or the patient is taking anticoagulants. Traffic accidents and sports activities are the most common mechanisms of injury.

**Clinical Presentation.** Compartment syndrome is a clinical diagnosis. In a conscious and fully oriented patient, pain that is disproportionate to the injury or physical findings is a hallmark finding in compartment syndrome. Pain often is characterized as deep, burning, and unrelenting and is difficult to localize. The need for increasing amounts of analgesics should not lead the emergency clinician automatically to the conclusion that the patient is drug-seeking; rather, it should serve as a prompt to the possibility that a compartment syndrome is developing or is present.

Pain on passive stretching of the muscle groups in the suggested compartment is an important finding. In addition, active flexion of involved muscles may produce pain. Other reliable suggestive signs and symptoms are hypoesthesias and paresthesias in the distribution of nerves crossing the compartment or tenderness, tenseness, or sensation of tightness of the compartment.

Skin color, temperature, capillary refill, and distal pulses all are unreliable monitors for compartment syndrome because the pressure necessary to produce compartment syndrome is well below arterial pressure. Pallor and loss of pulses are late and ominous signs. Diminished pulses should suggest concomitant pathologic conditions responsible for reduced arterial flow. Although it is still frequently taught that the five Ps—pain, pallor, pulselessness, paresthesias, and paralysis—are signs and symptoms of compartment syndrome, this is generally not true. Rather, they are the signs of acute disruption of arterial flow. Subjective complaints are an important indicator of compartment syndrome. Patients who are not fully alert or cooperative are assessed with particular care.

**Diagnostic Tests.** Clinical examination remains the diagnostic cornerstone of acute compartment syndrome, which can then be confirmed by the measurement of compartment pressure. Compartment pressures can be measured with a commercially available monitor (Fig. 42.7). The two most common methods of determining compartment pressures are the slit catheter techniques and side port needle. The Stryker Intra-Compartmental Pressure Monitor (Stryker, Kalamazoo, MI) system is a hand-held digital device that is easy to use with minimal training. Care should be taken to zero the monitor in on the plane in which it will be inserted to account for the effects of gravity. It is also paramount that the appropriate compartment be measured. Pressures of less than 30 mm Hg generally do not produce compartment syndrome. When intracompartmental pressures exceed 30 mm Hg, or when the difference between diastolic blood pressure and compartment pressure (perfusion pressure, also known as the ΔP) is less than 30 mm Hg, fasciotomy may be indicated. Serial or continuous pressure measurements should be performed in cases that are not clear-cut. A rising or sustained elevated compartment pressure is superior to a single measurement as an indicator of acute compartment syndrome or the need for fasciotomy. A compartment pressure greater than 30 mm Hg and perfusion

pressure less than 30 mm Hg have relatively poor specificity for compartment syndrome, and orthopedic consultation should be sought to help guide management.\textsuperscript{9}

Doppler ultrasound is not useful in evaluating these patients because excellent arterial blood flow may be documented, even in the presence of a significant compartment syndrome. Newer devices based on near-infrared spectroscopy (NIRS) measurement of tissue oxygenation have proven effective experimentally in detecting compartment syndrome but will require validation in the clinical setting before widespread application.

**Treatment, Complications, and Disposition.** Complete fasciotomy is the only treatment that can reliably normalize elevated compartment pressure. Preparation for surgery is done as quickly as possible. Delaying fasciotomy for more than 12 hours often results in irreversible myonecrosis and nerve damage. While the patient is awaiting definitive treatment, the affected part should not be elevated above the level of the heart because this maneuver does not improve venous outflow and reduces arterial inflow. Slight dependency has been suggested to maximize the pressure head in the extremity.

Because tissue compartments are more pliable soon after injury, the rate of extremity swelling is greater in the immediate postinjury period and tends to peak at 36 to 48 hours after injury. Although compartment syndrome usually appears within 36 hours of injury, cases have been reported more than 2 weeks following injury.\textsuperscript{7} Extremity swelling decreases over a similar duration. Rhabdomyolysis, hyperkalemia, and myoglobinuria may occur and should be managed aggressively to avoid renal failure. Lactic acid also is released from necrotic muscle tissue. Other complications include infection and tissue loss.

Delayed treatment results in loss of nerve and muscle function and eventual contracture formation. The magnitude of these disasters may be illustrated by the fact that in 2004, the average indemnity award in cases of missed compartment syndrome was nearly $426,000. Awards were proportional to the delay beyond 8 hours in performing fasciotomy and the number of the five Ps indicating ischemia that were present during the initial missed diagnosis. Thus, when the diagnosis of compartment syndrome is confirmed, fasciotomy should be done without delay.

**Avascular Necrosis**

Because of their blood supply, certain bones may undergo avascular necrosis after fracture, especially if fractures are comminuted and go untreated for any length of time. The femoral head, talus, scaphoid, lunate, and capitate are particularly prone to this complication. These injuries are described in subsequent chapters.

**Fat Embolism Syndrome**

Fat embolism refers to the presence of fat globules in the lung parenchyma and peripheral circulation after a long bone fracture or major trauma. The phenomenon of fat embolization is probably common as a subclinical event after long bone fracture. Intravascular fat droplets appear in nearly one of five patients admitted with major trauma, although not all patients are symptomatic or require treatment.

Fat embolism syndrome is a serious manifestation of fat embolism, occurring most commonly after long bone fractures (usually tibia and femur) in young adults and after hip fractures in older patients. Symptoms usually appear 1 to 2 days after an acute injury or after intramedullary nailing. Respiratory distress and hypoxemia are the earliest, most common manifestations. Acute respiratory distress syndrome (ARDS) may occur and is the usual cause of death. Neurologic involvement, presenting as restlessness, confusion, and/or deteriorating mental status, also is an early sign, as are thrombocytopenia and a petechial rash.\textsuperscript{10} Fever, tachycardia, jaundice, retinal changes, and renal involvement may occur. Fat is seen in the urine in 50% of patients within 3 days of injury. The incidence of full-blown fat embolism syndrome varies from 0.5% to 2% in patients with isolated long bone fractures to 5% to 10% in patients with multiple fractures. Management of fat embolism syndrome is primarily supportive, usually in an intensive care unit. The mortality rate is 20%, but most patients recover without severe sequelae. No specific therapy has shown benefit.

**Fracture Blisters**

Fracture blisters are tense blisters or bullae that accompany high-energy injuries, with significant soft tissue swelling. They can occur anywhere but are most common in areas with thin soft tissue envelopes. The ankle, elbow, foot, and knee (in that order) are the most common sites; all these contain fewer hair follicles and sweat glands to anchor together the epidermal-dermal junction than other limb locations. Fracture blisters are believed, in many cases, to occur in the setting of increased underlying tissue pressure and may be a harbinger of compartment syndrome.

Early reduction and splinting with expedited surgical intervention reduces the incidence of fracture blister formation. In addition, the presence of a fracture blister requires an alteration of the surgical approach or delay in surgery. Most experts discourage incisions through a fracture blister because such incisions seem to increase infection and skin breakdown. Measures to perform early surgery after high-energy injuries and minimize increases in tissue pressures might reduce the incidence of this complication. Intact blisters should be covered with povidone-iodine solution and a sterile dressing. Unroofing the blister and applying coverage with silver sulfadiazine paste has been reported to decrease the incidence of complications.

**Complications of Immobilization**

Fractures frequently result in long periods of immobilization. Immobility may lead to multiple medical problems, especially in older patients, including pneumonia, deep venous thrombophlebitis, pulmonary embolism, urinary tract infection, wound infection, decubitus ulcers, muscle atrophy, stress ulcers, gastrointestinal hemorrhage, and psychiatric disorders (Box 42.5). Early ambulation is a major goal of optimal orthopedic care.

**Damage Control Orthopedic Surgery**

Over the past few decades, the management of the multiply injured trauma patient has changed considerably. Historically, patients with multiple injuries were treated nonoperatively because it was believed they were too ill to tolerate surgery. In the 1970s, literature began to appear suggesting adverse outcomes as a result of prolonged recumbency. In addition, operative fracture fixation techniques were evolving, and this led to the advent of early fracture stabilization and the notion of early total care of the polytrauma patient. During the 1990s, the concept of damage control surgery came to the forefront of trauma surgical care. The successful use of an abbreviated operation in patients with penetrating abdominal trauma to avoid the lethal triad of hypothermia, acidosis, and coagulopathy was reported in 1993, and the term damage control was coined. Similar principles were found to be applicable to the management of pelvic and long bone fractures in the polytrauma patient.

With this change in approach, early total care with immediate definitive fixation of all major fractures gradually shifted to early temporary fracture stabilization, resuscitation of the patient to a stable physiologic state, and then definitive fixation at a later time once the patient’s physiology had been stabilized. Temporary
Some dislocations, such as anterior shoulder dislocation, cause an obvious deformity, whereas others, such as posterior shoulder dislocation, may be subtle. Swelling of soft tissues also may obscure the diagnosis, such as in the tarsal-metatarsal region. Gentle passive testing of range of motion should be performed but never forced. Assessment for neurovascular function is similar to that for fracture. Certain dislocations (e.g., knee) are so commonly associated with vascular injuries that a careful assessment of blood flow is important in evaluating these injuries.

Plain radiographic studies detect most dislocations, provided that the correct views are ordered. Radiographs should be performed before and after attempts at reduction of first-time or complicated dislocations unless there is neurovascular compromise. This confirms the diagnosis and ensures that associated fractures are documented before treatment is undertaken.

**SUBLUXATION AND DISLOCATIONS**

**Nomenclature**

Abnormal forces applied to joints may result in the loss of continuity between two articulating surfaces. Partial loss of continuity is termed subluxation, and complete loss is termed dislocation. In general, dislocations are named for the major joint involved, as in a dislocated shoulder or hip. In three-bone joints, the injury is named for the joint involved if the disturbance involves the two major bones or, if the lesser bone is involved, the disturbance is named for that bone. Separation of the femur from the tibia is termed dislocation of the knee, whereas displacement of the patella from its normal articulation is termed dislocation of the patella (Fig. 42.8). At the elbow, separation of the olecranon from the humerus is termed a dislocation of the elbow, whereas separation of the radius from the humerus is termed radial head dislocation.

Dislocations and subluxations should be described according to the direction of the distal segment relative to the proximal segment or of the displaced bone relative to the normal structures. The injury shown in Fig. 42.9 is termed dorsal dislocation of the interphalangeal joint of the thumb. Disruption of articulation also may occur in combination with a fracture. The term fracture-dislocation is used to describe this combination. If the overlying skin is broken in any way, dislocations, subluxations, or fracture-dislocations are described as open and constitute the same emergency as an open fracture alone.

**Assessment**

In most cases of dislocation, severe to excruciating pain is present because the highly innervated joint capsule is stretched or torn. Movement of the joint exacerbates the pain. This useful sign is lost in an obtunded, intoxicated, or unconscious patient and may result in a missed diagnosis if a careful survey is not performed.

Some dislocations, such as anterior shoulder dislocation, cause an obvious deformity, whereas others, such as posterior shoulder dislocation, may be subtle. Swelling of soft tissues also may obscure the diagnosis, such as in the tarsal-metatarsal region. Gentle passive testing of range of motion should be performed but never forced. Assessment for neurovascular function is similar to that for fracture. Certain dislocations (e.g., knee) are so commonly associated with vascular injuries that a careful assessment of blood flow is important in evaluating these injuries.

Plain radiographic studies detect most dislocations, provided that the correct views are ordered. Radiographs should be performed before and after attempts at reduction of first-time or complicated dislocations unless there is neurovascular compromise. This confirms the diagnosis and ensures that associated fractures are documented before treatment is undertaken.

**Treatment**

Methods of relocating specific joints are reviewed in subsequent chapters, but a few basic principles apply. In general, a joint should be relocated as soon as possible. Over time, swelling and muscle spasm make reduction more difficult. Also, pain is not adequately relieved until the dislocation is reduced. In the hip, early reduction is mandatory to restore vascular supply and avert the complication of avascular necrosis. The general principle of reducing a dislocation is to stabilize the proximal bone and re-create and reverse the mechanism of injury, pulling the proximal end of the dislocated bone out and away from whatever is trapping it in its final resting place. This technique helps prevent interposition of soft tissues in the joint that can preclude reduction. As this maneuver is accomplished, the disarticulated surface is

**BOX 42.5**

**Complications of Fractures and Immobility**

**FRACTURES**
- Hemorrhage
- Vascular injuries
- Nerve injuries
- Compartment syndrome
- Volkmann’s ischemic contracture
- Avascular necrosis
- Reflex dystrophy
- Fat embolism syndrome

**IMMOBILITY**
- Pneumonia
- Deep venous thrombosis
- Pulmonary embolism
- Urinary tract infection
- Wound infection
- Decubitus ulcers
- Muscle atrophy
- Stress ulcers

Fracture stabilization is usually accomplished by the application of external fixation devices to aid in hemorrhage control and tissue oxygenation, but the timing and optimal type of fracture surgery in the multiply injured trauma patient are still subjects of research.
SOFT TISSUE INJURIES

Sprains

Nomenclature

Ligamentous injuries resulting from an abnormal motion of a joint are termed sprains. A sprain is injury to the fibers of a supporting ligament of a joint. Sprains may be graded according to the severity of pathologic findings; clinically, however, the grades are often indistinct.

• First-degree sprains are characterized by minor tearing of ligamentous fibers, with resultant mild hemorrhage and swelling. Minimal point tenderness can be elicited. Stressing the ligament produces some pain, but there is no opening or abnormal joint motion.

• A second-degree sprain is a partial tear of a ligament, meaning that more fibers are torn than in the first-degree injury. Clinical findings include moderate hemorrhage and swelling, tenderness, painful motion, abnormal motion, and loss of function. There may be a tendency toward persistent instability and recurrence, and prevention of these complications is a major goal of treatment.

• A third-degree sprain describes the complete tearing of a ligament. Signs include a further exaggeration of the signs mentioned for second-degree sprain. In addition, stressing the joint, when possible and not limited by pain, reveals grossly abnormal joint motion, provided that this is not limited by pain or swelling.

Intraarticular analgesia and the evacuation of a hemarthrosis may be used to allow a more complete diagnosis of these injuries. Chronic joint instability may result if severe ligamentous injuries do not heal properly.

Assessment

The clinical presentation of a sprain of the extremity may be indistinguishable from that of a fracture. The injury frequently occurs during vigorous athletic activity, when forces applied in opposite directions result in a joint being stressed in an abnormal or exaggerated direction. The patient may complain of hearing a “snap” or a “pop” at the moment of injury and conclude that a fracture is present. Other patients report “seeing stars” or “almost passing out” at the moment the injury occurred and may still be in extreme pain, appearing pale and diaphoretic if seen shortly after the injury. Analgesia should be provided to these patients. Evaluation should include a careful history of the exact sequence of events at the time of injury and ascertaining the position of the extremity and the forces applied to it at that moment. A history of any sounds that accompanied the injury should be elicited. Examination of the joint should include stressing it to show abnormal motion. If radiographs are planned to rule out a fracture anyway, or if exquisite pain is produced by mild attempts to apply stress, it is probably better to delay stressing until films have verified the absence of a significant fracture. Plain radiography is indicated in some, but not all, cases to rule out a fracture.

Avulsion fractures may occur concomitantly with sprains. In children, epiphyseal fractures occur more commonly than ligamentous disruption because of the relative ligamentous strength compared with the ease of disrupting the epiphyses. Arthroscopy or MRI is indicated in the follow-up evaluation of some of these injuries (e.g., for suspected cruciate ligament tears) when significant pain or disability is present.

Treatment and Disposition

Specific management of sprains varies depending on the location and severity of the injury. In general, initial measures should include the traditional recommendations of ice, elevation, and analgesia. Nonsteroidal antiinflammatory drugs (NSAIDs) are effective analgesics in many patients. Several studies have found a more rapid decrease in swelling, increased exercise endurance, and earlier return to work with use of NSAIDs.

Immobilization through the use of one of the following methods provides protection and comfort in the initial management of most injuries. Because the severity of injury is sometimes difficult to establish at the first visit, it is reasonable to immobilize the affected joint for the first 48 to 72 hours, after which the extent of injury can be better determined. At that time, early mobilization is often desirable, particularly in lateral ankle injuries, because this leads to earlier return to work and athletic activities and better preservation of proprioceptive neuromuscular function. Use of an inflatable air cast, alone or in conjunction with an elastic ankle wrap, has been shown to be effective in decreasing the symptomatic period. For lower extremity injuries, protected weight-bearing with crutches provides patients with comfort and avoids motion of the impaired part. In older patients, safe ambulation sometimes cannot be accomplished, and a short hospitalization or respite in an acute rehabilitation or skilled nursing facility may be necessary.

For complete or nearly complete ligamentous disruption, urgent orthopedic consultation is mandatory. Less severe injuries can be followed up 3 to 7 days postinjury, when acute swelling has subsided. Physical therapy and rehabilitative exercises sometimes are begun at these visits and can be continued for several weeks. Because ligaments are relatively avascular, healing is slow, and patients with significant sprains should be informed of this. Sprains should be diagnosed as precisely as possible and should not be trivialized. Too often after radiographs have ruled out fracture of an affected extremity, the term sprain is applied indiscriminately or the patient is told that the injury is only a sprain, a misleading expression that should be avoided. Aside from creating false expectations regarding recovery, mislabeling of injuries not clearly visible on ED images may lead to missed occult fractures in adults or epiphyseal injuries in children.

Strains

Nomenclature

A strain is an injury to a musculotendinous unit resulting from violent contraction or excessive forcible stretch. The term pulled muscle sometimes is used interchangeably with muscle strain. These injuries are graded in a manner similar to sprains.

• A first-degree (mild) strain is a minor tearing of the musculotendinous unit, characterized by minor swelling, local tenderness, and minimal restriction of movement.

• Findings increase along a continuum such that in a second-degree (moderate) strain, more fibers are torn, but without complete disruption; swelling, ecchymosis, and loss of strength are more marked.
In a third-degree (severe) strain, the muscle or tendon is completely disrupted, with resultant separation of muscle from muscle, muscle from tendon, or tendon from bone.

An accompanying avulsion fracture may be present on radiographs in second- or third-degree injuries.

Assessment

Signs and symptoms include pain, ecchymosis, swelling, and loss of function. A force applied to the muscle, passive stress or active contraction, produces sharp pain at the site of injury, even as the injured muscle may be relatively comfortable at rest. A palpable defect sometimes is present at the site of a complete rupture, which usually involves the region of the muscle-tendon junction, or a bunching up of the muscle may be appreciated. Ultrasound had increasingly been used to diagnose an assortment of soft tissue injuries, including rotator cuff tears, tendon ruptures, and muscle tears. Among nonathletes, strains commonly are seen in patients who have overstressed a muscle group or tried to generate excessive force in an unconditioned muscle. Examples are the weekend gardener or mover who experiences lower back strain on Monday morning, the aerobics student who strains the rectus muscles, and the weightlifter with chest wall pain resulting from pectoralis major strain. These are usually first-degree injuries, and the onset is slow. Rapid acceleration (eg, in a tennis player) may result in a third-degree gastrocnemius or plantaris tear, whereas pushing off to jump is a common cause of rupture of the Achilles tendon in a basketball player. A sudden violent attempt at lifting by an older individual can result in a complete biceps brachii disruption. Sudden generation of forces, of which the thighs are capable, results in second-degree strain of the hamstrings, quadriceps, or thigh abductor muscles.

In athletes, generation of tremendous contraction forces coupled with excessive forcible stretching (while the body may be accelerating or planting) results in severe strains. Involvement of almost any muscle group is possible, and the onset of such injuries is usually acute. Immediate removal from activity, application of ice, and rest of the affected limb for 48 to 72 hours are usually advised for prevention of further injury. After a brief rest period, however, early mobilization and rehabilitation should be encouraged.

Treatment and Disposition

Treatment depends on the degree of disruption, location, and functional loss. Most first-degree injuries respond to rest, application of ice and, for some patients, analgesics in a few days. NSAIDs commonly are recommended and prescribed, although their efficacy for other than analgesic purposes is unproven.13 Second-degree strains are treated similarly, with protection against aggravating activity required for longer periods. Third-degree strains receive similar initial treatment in the ED plus early orthopedic consultation. Some of these injuries are amenable to surgical repair, whereas others may be treated with immobilization. The muscle affected and the age, occupation, and activity level of the patient all are factors in deciding whether surgical intervention is appropriate. Early mobilization is an important tenet in the treatment of muscle strains; its timing may be based on the ability to stretch the injured muscle as much as the uninjured contralateral muscle and the use of the injured muscle without pain during basic movements.

Tendinitis and Tendinosis

Tendinitis is classically described as an inflammatory condition characterized by pain at tendinous insertions into bone, occurring in the setting of overuse. It is now believed that the pathophysiology of this condition is more complex than mere overuse, with the roles of load and use affecting the cell-matrix interaction. Contributing factors are those associated with aging, decreased blood supply and decreased tensile strength, muscle weakness and imbalance, insufficient flexibility as well as male gender, obesity (in weight-bearing joints), smoking, malalignments, training errors, and improper equipment. In addition, certain systemic diseases, including diabetes mellitus, chronic renal failure, rheumatoid arthritis, and systemic lupus erythematosus, steroid use, and occasionally fluoroquinolone use are associated with the development of tendinopathy.

The histopathology of tendinitis is characterized by the following: degeneration and disorganization of collagen fibers; infiltration by macrophages, plasma cells, and lymphocytes rather than leukocytes; and increased vascularity. Inflammatory changes are not a principal finding in tendinitis. This evolving understanding of tendinitis should, in the future, allow for more logical treatment of these injuries aimed at the underlying pathophysiology. It also has led some authors to propose that chronic painful conditions of the tendon should be referred to as tendinosis rather than tendinitis or by other terms previously used to describe this condition, including tendinosis, degenerative changes, chronic tendinopathy, and partial rupture. In this chapter, the terms tendinitis and tendinosis are used interchangeably.

Common sites for tendinitis are the rotator cuff of the shoulder, Achilles tendon, radial aspect of the wrist (de Quervain’s tenosynovitis), and insertion of the hand extensors on the lateral humeral epicondyle (tennis elbow). Also commonly involved in athletes are the patellar tendon, particularly for those engaged in jumping sports, biceps femoris, semitendinosus, and semimembranosus (hamstring syndrome), posterior tibial tendon (shin splint syndrome), iliobibial band, and common wrist flexors (medial epicondylitis; involvement is seen in little league pitchers and golfers). In some locations, most commonly the shoulder, calcium deposition occurs along the course of the tendon, resulting in a painful condition termed calcific tendinitis. This condition also may occur in the wrist, hand, neck, hip, knee, ankle, or foot.

Physical examination reveals pain with motion and limitation of function and may include point tenderness and palpable crepitus over the involved tendon with motion. In general, a clinical test can be performed by forcible flexion of the involved muscle while keeping the point of insertion fixed or by operating the involved muscle against resistance. Either test should intensify the discomfort. Radiographs are usually negative. A small fleck of calcium may suggest an avulsion, or the surface of the bone at the attachment may be roughened, indicating periostitis. Calcium deposits along the course of the tendon due to calcific tendinitis should not be confused with an avulsion fracture. Ultrasound is sometimes useful in confirming the diagnosis of tendinitis. Although a normal tendon is characterized by a relatively homogeneous pattern, tendinosis is characterized by one or more of the following features: loss of the fibrillar echotexture, focal tendon thickening, diffuse thickening, focal hypoechoic area, irregular or ill-defined borders, or microruptures.

There is little evidence to support any specific treatment for tendinitis. The classic approach consists of rest, ice, and NSAIDs initially, followed by rehabilitation, training, and control of force loads to prevent recurrences. Although NSAIDs may be useful for a brief period as an analgesic, no evidence exists that they significantly alter the pathophysiology of this condition, and no rationale exists for ordering them in anti-inflammatory doses or for patients at any significant risk for complications from this class of drugs.11 Peritendinous local infiltration of anesthetics and corticosteroids may be useful but should not be repeated frequently because it may cause susceptibility to tendon rupture. Injection therapy is especially useful in calcific tendinitis around the shoulder. Injection of steroids directly into the Achilles tendon should be avoided.
because of reports of partial or complete rupture after even a single injection. Some cases of calcific tendinitis that do not respond to conservative therapy may require arthroscopic or open surgery.

**Bursitis**

Bursitis is a painful inflammation of the bursa that may be traumatic, infectious, or related to systemic illness. Commonly involved sites include the olecranon, greater trochanter of the femur, and prepatellar and anserine bursae around the knee. Physical findings are tenderness and swelling over the involved bursa. When accompanied by warmth and overlying erythema, an infection may be present. If infection is suggested, aspiration of the bursal fluid and Gram staining and culture are recommended. Otherwise, treatment may be conservative and is similar to treatment for tendinitis, with ice, NSAIDs, or steroid injections. Most patients can be treated as outpatients.

**TREATMENT MODALITIES**

**Splinting and Bandaging**

Suggested or confirmed fractures or dislocations should be splinted to avoid damage to muscles, nerves, vessels, and skin. Splinting also may restore blood flow to ischemic tissue by removing pressure caused by a bone fragment resting against a blood vessel. In addition, splinting may relieve the pain associated with movement of fracture fragments.

**Field Care**

Splinting should begin in the field because it reduces the risk of further neurovascular compromise, prevents a closed injury from being converted to an open one during transport, reduces the patient’s pain, and facilitates subsequent ED assessment and imaging. Numerous commercial devices are available, and most ambulances carry an assortment of immobilization devices (Fig. 42.10). Minimal equipment includes long and short backboards, cervical collars, sandbags, and extremity splints. A half-ring traction splint is also essential. Inflatable air splints are favored by some authors because they are convenient, easy to apply, transparent, and radiolucent and because they tamponade low-pressure bleeding. Others prefer to avoid these devices because theoretically they could contribute to the development of a compartment syndrome. If used, inflatable splints should be inflated only by mouth and to the point that still permits indentation by gentle finger pressure.

Field personnel should splint possible fractures before the patient is moved. Severely angulated long bone fractures should be reduced in the field before they are splinted. Splints should be applied in such a way as to immobilize the joints above and below the fracture site to avoid motion of the involved bone. The skin should be padded to avoid local necrosis, and the splint should be secured by use of a circumferential wrapping material. This material should allow for some expansion and should not be applied in a constricting manner.

**Emergency Department Care**

In the ED, the indications for splinting are the same as in the field. All splints should be checked and, if properly applied, need not be changed. If alternate traction is available, Hare traction that was applied in the field should be carefully removed in the ED because it may angulate femur fractures and result in decubitus ulcers over the ischium. Splinting or other immobilization is also used after diagnosis and treatment of injuries. In some cases, a splint is all that is needed for definitive treatment. Injuries other than sprains and fractures (eg, inflammatory and infectious processes, bites, burns, repaired injuries of muscle bellies or tendons) also benefit from immobilization. Splints also can be used to improve function, such as with wrist drop that accompanies radial nerve palsy. When the injury is immobilized, it is important to stress elevation of the affected part to avoid edema formation. Many different devices and materials are available. Some devices that are commonly used are described next.

**Upper Extremity**

**Sling-and-Swathe and Velpeau Bandages.** Sling-and-swathe and Velpeau bandages are useful in immobilizing the shoulder, humerus, and elbow. They are commonly used after reduction of dislocated shoulders and to treat impacted fractures of the humeral neck. The axillae should be padded and powdered to avoid skin maceration. A commercial shoulder immobilizer also is available and is useful after reduction of a shoulder dislocation. Its advantages are ease of application and ease of removal and reapplication by the patient for bathing. Although they may aid in healing, they are primarily placed for comfort and to decrease the incidence of re-injury.

**Clavicle Fractures.** Once commonly used for clavicle fractures, figure-of-eight clavicle splints have been abandoned because of an unfavorable benefit-risk profile. A simple sling of the arm...
on the affected side is sufficient to support the clavicle, improving healing immobilization and relieving pain.

**Plaster and Fiberglass Splints.** Well-fitting, customized plaster splints can be fashioned easily to immobilize the elbow, forearm, wrist, and hand. The advantage of these splints is the ability to mold them to an exact size and shape (eg, along the ulnar side of the forearm and hand to immobilize a midshaft fourth or fifth metacarpal fracture, the so-called gutter splint). Several commercially available products consist of multiple layers of plaster or fiberglass strips, inside a covering of foam and flannel, on a continuous roll that can be applied to any length. While the splint is still wet, a bandage is wrapped over it, and the splint is molded and held in the desired position as the plaster or fiberglass resin hardens. Curing of the fiberglass and plaster splints produces an exothermic reaction. To avoid burns, lukewarm water should be used for the splint and adequate skin padding applied.

**Forearm and Wrist Splints.** Numerous preformed splints are available for splinting fractures of the distal forearm and wrist. They are lightweight, neat, and easy to apply and are easily removed and replaced by the patient (Fig. 42.11).

**Lower Extremity**

Splinting methods for various lower extremity fractures, including hip, femoral shaft, knee, and lower leg, are described in the respective chapters. Commercially available knee immobilizers can be used after acute injuries to provide firm but not rigid stabilization of the knee. The device is essentially a foam cylinder with medial and lateral aluminum stays, attached by Velcro straps, and spanning the upper thigh to upper ankle. This device is commonly used after trauma to let the knee cool off until a better physical examination or diagnostic study can be performed in a few days.

Historically, the Jones dressing, a bulky dressing of cotton bandage and elastic wrap, applied in layers, was used for acute knee injuries, but it has been completely supplanted by knee immobilizers. The Jones dressing generally is used only after surgical procedures.

**Ankle.** Immobilization of the ankle can be accomplished by numerous means. Plaster or fiberglass splints can be used temporarily for the treatment of nondisplaced ankle fractures or severe sprains. These can be fashioned in the same manner as described for the upper extremity. An alternative method is to apply a full circular cast, bivalve it on either side, discard the anterior piece, and affix the posterior mold with an elastic bandage or bias-cut stockinet. Most ankle injuries should be splinted with the patient’s ankle in neutral position. Injuries to the Achilles tendon, plantaris muscle, or gastrocnemius muscle initially should be treated with the foot held in slight equinus (plantar flexion) for comfort. The toes should be free to move distal to the metatarsophalangeal joints, and the proximal border should end below the tibial tubercle to avoid pressure on the peroneal nerve.

Adhesive strapping is an alternative method of ankle immobilization that provides good support and limitation of motion. Taping reportedly loses its protective properties with cyclic loading and sweating; although this is cited as a disadvantage, it may actually be helpful in encouraging and allowing early mobilization. This method is lightweight and not bulky, and a shoe can be worn over the material. Tape is applied in a noncontinuous manner, which allows for swelling and avoids constriction. First, the hair is shaved. Next, strips of tape are measured and torn off; 1.5- or 2-inch cloth-backed adhesive tape or Elastoplast is used. Elastoplast is an elastic-backed tape, constructed to stretch only in the longitudinal direction; this serves to spring the foot back automatically to a neutral position if the foot is planter-flexed for any reason. The tape should be applied directly to the skin after a skin adherent, such as tincture of benzoin, is applied. The tape should lie flat because wrinkles may damage the skin (Fig. 42.12). The use of tape is associated with dermatologic complications, including itching or contact dermatitis, owing to adhesion of the tape to the skin. For moderate to severe lateral ankle sprains, a commercial mechanical support composed of molded plastic with Velcro straps (eg, AirCast Air Stirrup; DJO Global, Vista, CA) is more effective than elastic bandaging alone (Fig. 42.13).

The treatment of ankle sprains is discussed in Chapter 51.

**Casts**

Plaster or synthetic (fiberglass) casts perform a function similar to splints in that they provide stability and pain relief. Casts are not mandatory for all fractures and, in situations in which they are, application is usually not an immediate necessity. Because they are circumferential, casts provide more effective immobilization of a fracture, but they require more skill and time to apply.

Swelling and subsequent pressure under the cast are highest during the first 24 hours after injury. Complications of casting include compartment syndrome, thermal injury, pressure sores, bacterial and fungal infections (especially if a wound is present under the casted area), and pruritic dermatitis. Plaster is applied as strips or rolls of cloth impregnated with a hemihydrate of calcium sulfate. When this cloth is dipped in lukewarm water, a creamy paste is formed that can be molded into a cast. An exothermic reaction takes place that causes the plaster to harden and can burn the skin. Factors that have been shown experimentally to increase skin temperatures during plaster application are dip water temperatures greater than 24° C (75° F), cast thickness greater than eight sheets, and inadequate ventilation of the newly applied cast. Immersing the plaster in water for too short a time or squeezing too much water out also may lead to the generation
**Fig. 42.12.** A–D, Application of adhesive strips to immobilize the ankle.

**Fig. 42.13.** Air cast ankle support. A, Lateral view. B, Anterior view.
of excess heat. To avoid pressure on the skin and over bony prominences, stockinette and layers of cotton sheet wadding (Webril; Covidien, Minneapolis) are first applied snugly. Padding that migrates under a formed cast can be uncomfortable and result in pressure sores. Padding alone does not prevent burns.

Variations of the basic cast exist. A window may be placed in the cast, and the cutout area may be used for access to skin wounds that require care or observation during immobilization. Walking heels may be worked onto a lower extremity cast and should be placed in the center of the foot. Synthetic casts (fiberglass and other materials) are lightweight, durable, and water-resistant. In addition, their setting temperatures are significantly lower, and they are less likely to produce burns.

Patients with casts may visit the ED for complaints related to their casts; these usually are pain, local irritation, swelling, or numbness of the distal part. A cast that is too tight results in swelling, pain, coolness, and change in skin color of the distal parts. Pain also may be caused by the initial injury or by local pressure or may be a result of a developing compartment syndrome or wound infection. When a patient complains of pain, it is prudent to bivalve the cast and inspect the extremity. This is done by cutting the plaster and padding on each side and removing half the cast at a time, with the other half used as a mold to keep the extremity immobile. Afterward, the bivalved cast can be held together with bias-cut stockinette or elastic wrap until a new cast is applied. If relieving external pressure does not alleviate symptoms, the diagnosis of compartment syndrome should be considered. Casts may obscure wound infections, sources of sepsis, and even the source of tetanus.

Although once routine, we recommend basing the need for cast checks 1 day after initial application on the type and risk of the fracture and reliability of the patient and his or her access to follow-up care.

**KEY CONCEPTS**

- Consultation with an orthopedist should be sought for the treatment of most long bone fractures, open fractures, injuries with joint violation, and injuries with neurovascular compromise.
- A careful history and physical examination can predict radiographic findings with a high degree of accuracy. A presumptive diagnosis before a radiographic study may prompt the emergency clinician to order special views necessary to diagnose an injury correctly.
- Open fracture management should focus on the early administration of antibiotics, tetanus prophylaxis, coverage of the wound, and splinting of the extremity. Suggested therapy for open fractures includes a first-generation cephalosporin, such as cefazolin, with the addition of an aminoglycoside for type II or III open fractures.
- Compartment syndrome is associated most commonly with a closed long bone fracture of the tibia but also is well described in the thigh, forearm, arm, hand, and foot and can occur with soft tissue trauma alone. Clinical examination remains the diagnostic cornerstone of acute compartment syndrome, which can then be confirmed by compartment pressure measurement.
- Because of their blood supply, certain bones may undergo avascular necrosis after fracture, especially if fractures are comminuted and go untreated for any length of time. The femoral head, talus, scaphoid, and capitane are particularly prone to this complication.
- Fat embolism syndrome is a serious consequence of fat embolism, occurring most commonly after long bone fractures in young adults (usually tibia and fibula) and after hip fractures in older patients. ARDS is the earliest, most common, and serious manifestation. Neurologic involvement, manifesting as restlessness, confusion, or deteriorating mental status, is also an early sign, as are thrombocytopenia and a petechial rash.

CHAPTER 42: QUESTIONS & ANSWERS

42.1. A 6-year-old girl presents complaining of pain in her right ankle after tripping and falling in the playground. On physical examination, you note that there is moderate swelling and diffuse tenderness of the lateral ankle joint, with good pulses and normal sensation. Radiographs of the ankle do not demonstrate an acute fracture or disruption of the growth plates. What is the next step in this patient’s management?

A. Ace wrap, ice, pain medication, and orthopedic referral
B. Emergent orthopedic consult and preparation for the operating room
C. Orthopedic referral, ice, and pain medication
D. Splint, pain medication, and orthopedic referral
E. Urgent orthopedic consult, ice, and pain medication

Answer: D. A child with swelling and tenderness over an epiphysis (eg, of the lateral ankle) and a negative radiograph should be suspected to have an epiphyseal injury, rather than a sprain, because the epiphysis is weaker than the overlying ligaments.

42.2. Which of the following situations requires an emergent fasciotomy in the setting of a clinically suspected compartment syndrome?

A. Elevated tissue pressure within a closed compartment
B. Pain on passive stretching of the muscle group involved
C. Tissue pressure less than the diastolic pressure
D. Tissue pressure of 20 mm Hg
E. Tissue pressure within 30 mm Hg of the mean arterial pressure

Answer: A. Controversy exists regarding attempts to define compartment syndromes based on tissue pressure. The tolerance to tissue ischemia varies among individuals because of shock, compensatory hypertension, altered tone in resistance vessels, and other unknown factors. Inadequate perfusion and relative ischemia begin when the tissue pressure within a closed compartment increases to within 20 mm Hg of a patient’s diastolic pressure or, more accurately, within 30 mm Hg of the mean arterial pressure. When tissue pressure equals or exceeds the patient’s diastolic pressure, tissue perfusion effectively ceases.

42.3. Which of the following is not a manifestation of fat embolism syndrome?

A. Altered mental status
B. Hematochezia
C. Petechial rash
D. Respiratory distress
E. Thrombocytopenia

Answer: B. Respiratory distress and hypoxemia are the earliest, most common manifestations of fat embolism syndrome. Acute respiratory distress syndrome (ARDS) may occur and is the usual cause of death. Neurologic involvement, manifesting as restlessness, confusion, or deteriorating mental status, also is an early sign, as are thrombocytopenia and a petechial rash. Fever, tachycardia, jaundice, retinal changes, and renal involvement may occur.
CHAPTER 43
Hand
Dana A. Stearns | David A. Peak

PRINCIPLES
Function of the hand may be impaired by injury or illness, particularly infection or inflammation. Effective and timely evaluation and treatment require an in-depth knowledge of the anatomy of the hand and wrist, including the vascular and nerve supply and location and functions of muscles and tendons acting on the joints in the hand. Serious injury, with potential long-term consequences, may appear innocuous until detailed functional testing reveals tendon or nerve disruption. Deep space infections, improperly treated, can cause permanent disability. Methodic evaluation will identify the conditions and injuries best managed in consultation with a hand surgeon (Box 43.1).

Anatomy
Five digits, including the thumb and four fingers, extend from the hand—the second digit (index finger), third digit (middle [long] finger), fourth digit (ring finger), and fifth digit (little finger; Fig. 43.1). Each finger contains three phalanges, the thumb only two. Each finger has a proximal (PIP) and distal (DIP) interphalangeal joint. The thumb has only a single interphalangeal (IP) joint. These joints articulate through 1 degree of freedom (flexion-extension). All digits possess a metacarpophalangeal (MCP) joint at the palmar interface, which articulates through two degrees of freedom (flexion-extension, adduction-abduction). The distal aspect of the proximal and middle phalanges are bicondylar, creating a grooved and articular surface that provides stable flexion and extension. Each joint capsular matrix contains articular synovium. Alongside the MCP and IP joint capsules, lateral and medial collateral ligaments maintain joint alignment during motion. The IP collateral ligaments insert onto a fibrocartilaginous matrix across the volar base of the IP joint known as the volar plate. IP ligaments that are stretched due to injury may lead to joint instability. Recovering MCP joints are best placed in flexion for the same reason (Fig. 43.6).

Pediatric phalangeal and thumb metacarpal bony epiphyses are located proximally, whereas the finger metacarpals are distal (see Fig. 43.1). They begin to appear radiographically between 10 and 24 months; fusion with radiographic evidence of skeletal maturity is age-specific and occurs during adolescence (ages 14–16 years).

Muscles and Tendons
Intrinsic hand musculature originates within the hand itself, whereas the extrinsic musculature extends from the volar and dorsal aspects of the forearm, with their tendons extending to insertion points on the hand and digits.

Intrinsic Musculature. There are four groups of intrinsic hand muscles—thenar, hypothenar, interosseous, and lumbrical. The thenar and hypothenar musculature assist with thumb and fifth digit flexion, abduction, and opposition. They take their origin on the palmar aspect of the carpal scaphoid, trapezium (thenar), pisiform, hamate (hypothenar) carpal, and flexor retinaculum (Fig. 43.7). They insert on the first and fifth metacarpal and proximal phalanges, respectively, and are named for their function. The interosseous muscles originate on the palmar and dorsal aspects of the metacarpal bones and insert on the ipsilateral side of the corresponding proximal phalanges (Fig. 43.8). The three palmar interosseous muscles adduct the index, ring, and little fingers against the long finger. The four dorsal interossei abduct these three digits away from the long finger. The lumbricals originate on the proximal finger metacarpal bones and tendon sheath of the corresponding flexor digitorum profundus (FDP) tendons. They insert on the tendinous-ligamentous matrix known as the extensor expansion that forms a hood over the PIP joints of the four fingers. The lumbricals assist with finger MCP joint flexion and IP joint extension (see Fig. 43.8).
CHAPTER 43  Hand

Hand Extensor Tendons.
Nine extensor tendons pass from the dorsal forearm and cross the carpal wrist underneath the extensor retinaculum through six fibrous compartments that prevent bowing of the tendons during extension (Fig. 43.9). These compartments extend medially across the radius and ulna. The thumb’s extensor pollicis longus tendon, contained in the third compartment, curves radially around a fibro-osseous prominence on the distal radius known as Lister’s tubercle, passing to the dorsum of the thumb’s distal phalanx and extending the thumb’s DIP joint. This and the first compartment’s tendons assist in the creation of the radial fossa known as the anatomic snuffbox.

Extrinsic Musculature. The dorsal forearm contains wrist extensors and deviators, thumb extensor and abductors, and finger extensors. Each of these muscles are named for their function.

The volar forearm contains wrist flexors and deviators, as well as thumb and finger flexors. Their tendons pass to the carpal region inserting there and on associated proximal metacarpals or passing through the carpal tunnel and into the hand. The exception is the palmaris longus tendon; absent in up to 25% of the population, it passes anterior to the flexor retinaculum and forms the palmar aponeurosis (see Fig. 43.3). This tendon is commonly injured in soft tissue lacerations at the volar wrist.

BOX 43.1
Potential Limb-Threatening Conditions Requiring Immediate Intervention and Emergency Hand Consultation

- Compartment syndrome
- Crush injuries
- High pressure injection injury
- Open fracture
- Amputation
- Vascular injury
- Limb-threatening infection (includes bites and risk of tendon, neurovascular or joint)
- Burns—thermal, chemical (especially circumferential burns)
- Dislocations (eg, carpometacarpal joint fracture-dislocation)
- Complex fractures (angled, oblique or malrotated fractures)

NON–LIMB-THREATENING CONDITIONSa

- Closed fractures
- Nerve injury
- Tendon injury
- Ligamentous injury
- Distal phalanx injury (includes amputation, tuft, nail bed)

*These conditions typically need definitive intervention and urgent consultation assistance with disposition (24–72 hr).

Extrinsic Musculature. The dorsal forearm contains wrist extensors and deviators, thumb extensor and abductors, and finger extensors. Each of these muscles are named for their function.

The volar forearm contains wrist flexors and deviators, as well as thumb and finger flexors. Their tendons pass to the carpal region inserting there and on associated proximal metacarpals or passing through the carpal tunnel and into the hand. The exception is the palmaris longus tendon; absent in up to 25% of the population, it passes anterior to the flexor retinaculum and forms the palmar aponeurosis (see Fig. 43.3). This tendon is commonly injured in soft tissue lacerations at the volar wrist.

Extensor Tendons. Nine extensor tendons pass from the dorsal forearm and cross the carpal wrist underneath the extensor retinaculum through six fibrous compartments that prevent bowing of the tendons during extension (Fig. 43.9). These compartments extend medially across the radius and ulna. The thumb’s extensor pollicis longus tendon, contained in the third compartment, curves radially around a fibro-osseous prominence on the distal radius known as Lister’s tubercle, passing to the dorsum of the thumb’s distal phalanx and extending the thumb’s DIP joint. This and the first compartment’s tendons assist in the creation of the radial fossa known as the anatomic snuffbox,
Fig. 43.2. Hand anterior, palmar-volar view. A, Superficial landmarks and nomenclature. Anatomic position places the thenar eminence and thumb lateral and farthest from the midline. Skin creases are created on the skin surface near joint articulations and labeled for their anatomical position. B, Close relationship of the neurovascular and musculotendinous structures and their proximity to the skin surface. The distal (D), middle (M), and proximal (P) finger and thumb phalanges are labeled. The neurovascular bundles (NVB) pass from the palm to each digit and travel alongside the digital tendons (T). Synovial sheaths surround the digital tendons and adhere to the anterior surface of the digital phalanges. (Courtesy Dr. D.A. Stearns, Department of Emergency Medicine, Massachusetts General Hospital, Harvard Medical School, Boston.)

Fig. 43.3. Palmaris longus tendon—palmar aponeurosis. A, The palmaris longus tendon (blue arrow), absent in up to 25% of the population, contributes to the palmar aponeurosis (dotted outlines).
Fig. 43.3, cont’d. B, Superficial layer of muscles in the palm of the hand, right side, palmar view. There are three groups of muscles in the palm of the hand. On both sides of the palm, muscles of the thumb and fifth finger form the thenar and hypothenar, respectively. Between the two groups are the muscles of the palm of the hand. These three groups are arranged in three consecutive muscle layers. The neurovascular structures between these layers need to be considered when dissecting the palm of the hand. Located most superficially is the palmar aponeurosis, which consists of longitudinal and transverse fibers; the latter is prominent just below the metacarpophalangeal joints (superficial transverse metacarpal ligament). The palmar aponeurosis is fixed proximally to the flexor retinaculum and stretched by the palmaris longus. Distally, it is fixed to the tendinous sheaths of the finger flexors and to the ligaments of the metacarpophalangeal joints. At the thenar, the abductor pollicis brevis is located on the radial side and the flexor pollicis brevis is located ulnar to the abductor muscle. At the hypothenar, the palmaris brevis and abductor digitii minimi are superficial. (A courtesy Dr. D.A. Stearns, Department of Emergency Medicine, Massachusetts General Hospital, Harvard Medical School, Boston; B from Paulsen F, Waschke J, editors: Upper extremity. In Sobotta atlas of human anatomy, vol 1, ed 15, Munich, 2013, Urban & Fischer, pp 130–245. © Elsevier, 2013.)
Fig. 43.4. Hand, dorsal view. A, Superficial landmarks and nomenclature. B, Distal (D), middle (M), and proximal (P) finger and thumb phalanges. The extensor tendon apparatus (T) passes to their respective digits along the dorsal surface of the bones, just deep to the skin and subcutaneous tissues. C, The skin is less loosely affixed across the dorsal surface. D, Significant dorsal swelling. The cause was an innocuous puncture wound to the first web space that extended posteriorly. (Courtesy Dr. D.A. Stearns, Department of Emergency Medicine, Massachusetts General Hospital, Harvard Medical School, Boston.)
Fig. 43.5. A, Sagittal and transverse views of the longitudinal proximal and distal metacarpal arches. B, Longitudinal arch. C, Proximal transverse arch. D, E, Unique thumb articulations contribute to the intrinsic arches to create a broad range of grasp positions. (A from American Society for Surgery of the Hand: Regional review course in hand surgery syllabus, ed 10, Aurora, CO, 1990, American Society for Surgery of the Hand; B-E courtesy Dr. D.A. Stearns, Department of Emergency Medicine, Massachusetts General Hospital, Harvard Medical School, Boston.)
Fig. 43.6. A, The metacarpal head of the metacarpophalangeal (MCP) joint has an eccentric shape (blue arrow). The distance A-A₁ (MCP joint extension) is less than A-A₂ (MCP joint flexion), creating more collateral ligament tension with flexion than in extension. B, The lumbricals assist with finger metacarpophalangeal flexion and IP joint extension. C, When these ligaments are immobilized, they should be placed in a foreshortened position to reduce future joint instability and ensure proper alignment through its range of motion during rehabilitation. C, Recovering MCP joints are best placed in flexion and corresponding interphalangeal (IP) joints in extension. D, The lumbral musculature takes origin on the tendon sheath of the corresponding flexor digitorum profundus (FDP) tendons (red arrow). They insert on the tendinous-ligamentous matrix known as the extensor expansion that forms a hood over the proximal interphalangeal (PIP) joints of the four fingers (yellow arrows). Note the eccentric shape of the metacarpal head of the MCP joint (blue arrow). (A from DeLee JC, Drez D Jr. Orthopedic sports medicine: principles and practice, ed 2, Philadelphia, 2003, Saunders; B–D courtesy Dr. D.A. Stearns, Department of Emergency Medicine, Massachusetts General Hospital, Harvard Medical School, Boston.)
Fig. 43.7. Thenar (T) and hypothenar (H) musculature (A–C) assist with thumb and fifth digital flexion (D, H, I), abduction (E), adduction (H, I), and opposition (F, G). Opposition is the best test for recurrent median nerve function. If the nerve is damaged, the thumb can no longer oppose to the fifth digit tip. F, G asked to oppose, the patient with this injury will adapt by flexing and adducting the thumb to the base of the fifth digit, indicative of injury (H, I). (Courtesy Dr. D.A. Stearns, Department of Emergency Medicine, Massachusetts General Hospital, Harvard Medical School, Boston.)
PART II

The deviate abduct the towards digits longus serve away from the pollicis to finger. The radially Four Anatomic tendon interossei dorsal to adjacent extensor middle (Froment’s paper sign). E, F, Lumbrical function—flexion of the metacarpophalangeal (MCP) joint while extending the proximal interphalangeal (PIP) joint (“ta-ta” wave motion). (From Froment J: La préhension dans les paralysies du nerf cubital et le signe du pouce. Presse Med 1915; 23:409, 1915; and courtesy Dr. D.A. Stearns, Department of Emergency Medicine, Massachusetts General Hospital, Harvard Medical School, Boston.)

Fig. 43.8. A, Four dorsal interossei serve to abduct the adjacent digits away from the middle finger. B, The three volar interossei adduct them against the middle finger. Both sets of muscles are innervated by the ulnar nerve. C, Paper pinch test creating forceful adduction to prevent a sheet of paper from being drawn from between the digits. D, With ulnar nerve dysfunction, the patient will adapt to create resistance by flexing the thumb interphalangeal (IP) joint to pinch the paper, this uses the median nerve (Froment’s paper sign). E, F, Lumbrical function—flexion of the metacarpophalangeal (MCP) joint while extending the proximal interphalangeal (PIP) joint (“ta-ta” wave motion). (From Froment J: La préhension dans les paralysies du nerf cubital et le signe du pouce. Presse Med 1915; 23:409, 1915; and courtesy Dr. D.A. Stearns, Department of Emergency Medicine, Massachusetts General Hospital, Harvard Medical School, Boston.)

Fig. 43.9. Anatomic dissection exposing the six compartments for the dorsal forearm tendon after the extensor retinaculum has been removed. The sixth compartment is behind the fifth in this image and out of view. Note the bowing of the tendons after they have been released from the sheaths. Compartment 1, Abductor pollicis longus and extensor pollicis brevis; compartment 2, extensor carpi radialis longus and extensor carpi radialis brevis; compartment 3, extensor pollicis longus; compartment 4, extensor digitorum; compartment 5, extensor digiti minimi; compartment 6 (diagrammed but out of view, just medial to compartment 5), extensor carpi ulnaris. The red arrow notes the location of Lister’s tubercle, allowing the extensor pollicis longus tendon to deviate radially towards the thumb. (Courtesy Dr. D.A. Stearns, Department of Emergency Medicine, Massachusetts General Hospital, Harvard Medical School, Boston.)

created when the thumb is extended and abducted (Figs. 43.10 and 43.11). The superficial branch of the radial nerve courses over this location. Within the snuffbox lies the cephalic vein (internal’s vein), dorsal radial artery, and scaphoid carpal bone.

The extensor indicis and extensor digiti minimi tendons pass to the index and little fingers, providing each with independent extension function. The extensor indicis proprius and extensor digiti minimi can be independently tested by asking the patient to extend these digits after making a fist (Fig. 43.12). Juncturae tendineae connect adjacent tendons of the extensor digitorum communis (EDC) and extensor digiti minimi together in a horizontal and oblique orientation as these tendons approach the MCP joint. In addition to evenly spacing the tendons and stabilizing the MCP joints, the juncturae tendineae ensure continued individual MCP joint extension, even in the setting of traumatic transection of an extensor tendon.

The extensor complex on the dorsum of the four fingers is comprised of tendinous extensions from the extrinsic and intrinsic musculature (Fig. 43.13). As the EDC tendon crosses the MCP joint, it inserts onto the extensor apparatus joined by tendinous extensions from the interosseous and lumbrical musculature, creating the dorsal expansion (hood). The expansion divides into three bands—a central tendon (central slip) that inserts on the dorsal base of the middle phalanx and two lateral bands. The
**Fig. 43.10.** A, B. Dorsal forearm tendons extending across the wrist and hand dorsum beyond the extensor retinaculum. A. The superficial branch of the radial nerve (A) extends beyond the brachioradialis in the forearm and crosses over the anatomic snuffbox to supply the radial aspect of the hand dorsum. Note the bowing effect on the extensor tendons (B) after the tethering effect of the extensor retinaculum has been removed. B, Note Lister’s tubercle (arrow). (Courtesy Dr. D.A. Stearns, Department of Emergency Medicine, Massachusetts General Hospital, Harvard Medical School, Boston.)

**Fig. 43.11.** Anatomic snuffbox. Shown are the borders of the anatomic snuffbox (red triangles) and abductor pollicis longus, extensor pollicis brevis, and extensor pollicis longus (red arrows). The area is best palpated when the thumb is abducted and the metacarpophalangeal (MCP) joint is extended, as shown in the image at left. Also shown are the cephalic (intern’s) vein that passes over the snuffbox (blue arrows). Right, Superficial branch of the radial nerve supplying sensation to the hand dorsum (yellow arrows). The dorsal extension of the radial artery (red R) and scaphoid bone (green S) are palpable within the fossa. (Courtesy Dr. D.A. Stearns, Department of Emergency Medicine, Massachusetts General Hospital, Harvard Medical School, Boston.)
lateral bands combine with extensions of the lumbrical and interosseous tendons, cross the dorsum of the PIP joint, and insert on the dorsal base of the distal phalanx. The central and lateral bands are held in place by a transverse retinacular ligament, which serves to prevent the lateral bands from migrating anteriorly, resulting in paradoxical PIP joint flexion.

The EDC, interosseous, and lumbral tendons coordinate PIP and DIP joint extension. The intrinsic tendons travel volar to the axis of rotation of the MCP joint to insert on the lateral bands of the extensor apparatus. This unique position allows the intrinsic muscles to act as flexors at the MCP joint and as extensors at the PIP and DIP joints. The long extensors act primarily to extend the MCP joints. The relationship between the long flexors, long extensors, and lumbricals is complementary and aids in examination of the function of the fingers. On the palmar side, the long tendons flex the IP joints, and the lumbral flexes the MCP. On the dorsum, the reverse is the case: the long extensors extend the MCP, and the lumbrae extend the IP joints. This also helps explain why the preferred splinting position of MCP fractures is MCP flexion and PIP extension (see Fig. 43.13). Thumb extension is achieved through the use of the extensor pollicis longus (IP joint) and brevis (MCP joint).

**Flexor Tendons.** From the anterior forearm muscles, 12 tendons extend to the volar palm and digits. Facilitating wrist flexion and radial-ulnar deviation, the flexor carpi radialis, flexor carpi ulnaris, and palmaris longus tendons cross the carpal region to insert on the first metacarpal bone, fifth metacarpal bones, and palmar aponeurosis, respectively. The flexor digitorum superficiales (FDS), FDP, and flexor pollicis longus (FPL) tendons travel alongside the median nerve through the carpal tunnel and into the hand palm (Fig. 43.14). The FPL inserts on the volar aspect of the thumb’s proximal distal phalanx. As its name implies, the FDS lies more superficially in the palm than the FDP tendons (Fig. 43.15). Uniquely, the FDS tendons bifurcate just proximal to their insertion points at the volar base of each finger’s middle phalanx. This allows the FDP to pass through the gap and insert on the volar base of the corresponding finger’s distal phalanx (Fig. 43.16). The lumbral muscles originate on the corresponding fingers’ FDP tendons as they cross the metacarpals (see Fig. 43.15). Along the volar aspect of the hand, synovial sheaths encase tendons, minimizing friction of motion (Fig. 43.17).

Each digit’s muscle-tendon unit should be tested individually. Examination of extensor function involves observation of these digits separately and as a unit with the remaining digits. The flexor
Fig. 43.13. Finger extensor complex. A, B. The extensor tendon (ET) at the metacarpophalangeal (MCP) joint is secured by a sagittal band originating from the volar plate and metacarpal ligaments to form the origin of the extensor hood or expansion. A. The intrinsic tendons from the lumbrical (L) and interosseous (I) muscles join the extensor mechanism along the proximal dorsal phalanx. C, D. The extension complex at the proximal interphalangeal (PIP) joint is comprised of a trifurcation of the extensor tendon into a central slip (CS), which inserts on the dorsal base of the middle phalanx and two lateral bands (LB). These lateral bands continue distally beyond the distal interphalangeal (DIP) joint to insert at the dorsal base of the distal phalanx. C, E, F. The PIP extension mechanism is maintained in place over the PIP joint by the transverse and triangular retinacular ligaments. These prevent the lateral bands from migrating anteriorly, resulting in paradoxical PIP joint flexion. F. The index finger’s PIP joint is paradoxically flexed with DIP extension (boutonnière deformity). (A, D–F courtesy Dr. D.A. Stearns, Department of Emergency Medicine, Massachusetts General Hospital, Harvard Medical School, Boston; B, C from Doyle JR: Extensor tendons—acute injuries. In Green DP, editor: Operative hand surgery, New York, 1993, Churchill Livingstone, p 1928.)
Emergency

Stearns, Medicine, (Courtesy D.A. Dr. General Department Massachusetts Hospital, Harvard Medical School, Boston.)

Fig. 43.14. The flexor digitorum superficialis (FDS), flexor digitorum profundus (FDP), and flexor pollicis longus (FPL) tendons travel alongside the median nerve (yellow stars) through the carpal tunnel and into the hand palm. The ulnar nerve (purple stars) enters the palm through Guyon’s canal, just medial to the pisiform bone. The flexor tendons enter the synovial sheaths (SS) for each digit. Note the sheaths for the second through fourth digits begin just proximal to the respective MCP joints. The thumb and little finger’s sheaths extend from the proximal palm and are surrounded by muscles of the thenar and hypothenar eminences. (Courtesy Dr. D.A. Stearns, Department of Emergency Medicine, Massachusetts General Hospital, Harvard Medical School, Boston.)

carpi radialis, flexor carpi ulnaris, and palmaris longus tendons can be tested by palpating the tendons while the patient is flexing the wrist against resistance. The flexor pollicis longus assists in flexion of the MCP and IP joints and is assessed by observing the thumb’s IP joint flex against resistance.

Reduced resistance strength or increased pain and tenderness at a point along a tendon may suggest a partial tendon tear. Trigger finger can result from scarring of a previous tear and commonly occurs over the MCP joint. The patient may describe a pop or snap sensation as a tendon defect passes along the synovial sheath. At times, the patient may need to unlock the so-called trigger by palpating or ranging the affected digit with the opposite hand.

Synovial Spaces. Synovium-containing fibrous tissue sheaths provide lubrication for the flexor tendons as they pass the length of the digits to their insertions. Up to 100 degrees of flexion can occur at the PIP and 80 degrees at the DIP joints (Fig. 43.18; see Figs. 43.16 and 43.17). Adjacent bursae absorb repetitive and compressive forces. Tendons are largely avascular and depend on adjacent compartments for nutrition and homeostasis. The vascularity of the synovial sheaths and bursae promote the spread of infection. Extensor tendons, not encased in similar sheaths, are less prone to infectious tenosynovitis.

The synovial sheaths of the index, middle, and ring fingers pass from the distal phalanx along the volar digit into the palm, end at the distal palmar crease, and do not communicate with one another. The sheath and bursa of the thumb’s flexor pollicis longus tendon pass from the volar distal phalanx to the proximal palmar crease, where they may communicate with the adjacent radial bursa that resides in the palm and carpal tunnel (Fig. 43.19). A similar sheath and bursal space passes along the trajectory of the flexor digitorum tendons and communicates with the ulnar bursa in the palm and carpal tunnel. Infections involving the flexor synovial spaces of the index, middle, and ring fingers may extend along the volar aspect of the affected digit into the palm. Processes involving the thumb or little finger have the potential to extend into the carpal tunnel and may even communicate across to the opposite digit’s space, producing a horse-shoe infection.

Blood Supply

Arterial System. The radial and ulnar arteries, named for the forearm bones that they parallel, enter the carpal region at the wrist. The radial artery divides at the volar wrist. The superficial palmar branch moves anteriorly over the palmar carpal ligament and into the base of the thenar eminence, where it forms the superficial palmar arch. The radial artery passes to the dorsum of the trapezium bone between the radial styloid process and the scaphoid bone, where it emerges within the anatomic snuffbox and forms a dorsal carpal arch that parallels the extensor retinaculum. The deep branch passes into the hand palm between the first and second metacarpals to join the deep palmar arch (Fig. 43.20). The ulnar artery passes into the palm by crossing over the flexor retinaculum in a space created by the pisiform bone and palmar carpal ligament, known as Guyon’s canal. As it emerges from the canal, the artery sends a deep branch that forms a collateral with the radial artery’s deep palmar arch and continues anteriorly into the palm to form a collateral with the radial artery’s superficial palmar arch (Fig. 43.21; see Fig 43.20). Individual pairs of palmar digital arteries extend from these arches along the radial and ulnar
**Fig. 43.15.** The flexor digitorum superficialis tendons (FDS, 2–5) enter the palm through the carpal tunnel (tendons 3 and 4 tightly overlap anterior to tendons 2 and 5; the middle and ring fingers’ FDS are more commonly involved than the index and little fingers with carpal penetrating injuries as a result) and remain just anterior to the flexor digitorum profundus (FDP) tendons (2–5) in the palm and proximal phalanx. The flexor pollicis longus (FPL) inserts on the volar aspect of the thumb’s proximal distal phalanx. The fingers’ lumbricals (L) originate on the FDP tendon as they cross the metacarpals. They insert on the tendinous-ligamentous matrix known as the extensor expansion (EE) that forms a hood over the PIP joints and dorsal proximal phalanges of the four fingers. The lumbricals assist with finger MCP flexion and IP joint extension. The flexor tendons are encased in fibrous tissue synovial sheaths (SS) as they pass the length of the digits to their insertions. (Courtesy Dr. D.A. Stearns, Department of Emergency Medicine, Massachusetts General Hospital, Harvard Medical School, Boston.)
Fig. 43.16. A, The flexor digitorum superficialis (FDS), flexor digitorum profundus (FDP), and flexor pollicis longus (FPL) travel with the medial nerve through the carpal tunnel, extending through the palm towards their respective digits. B, Tendon trajectories of the FDS and FDP in the finger. C, The FDS tendons lie more superficially in the palm than the FDP tendons. The FDS tendons bifurcate just proximal to their insertion points at the volar base of each finger’s middle phalanx (red dotted lines). This allows the FDP to pass through the gap and insert on the volar base of the corresponding finger’s distal phalanx (joints labeled in blue). The FDS tendons are the first at risk with volar penetrating wounds involving the palm and proximal phalanges. The FDP tendon is particularly at risk with volar penetrating injuries of the middle and distal phalanges. Note the origin of synovial sheaths of the second through fourth digits (SS, arrows). (A, C courtesy Dr. D.A. Stearns, Department of Emergency Medicine, Massachusetts General Hospital, Harvard Medical School, Boston; B from Schneider LH: Flexor tendon injuries, Boston, 1985, Little, Brown.)

Fig. 43.17. A, Flexor tendon synovial sheath extending the length of the index and middle fingers along the volar digits. The middle finger sheath has been removed to expose the flexor tendons, as shown. The flexor digitorum superficialis (FDS) tendons bifurcate just proximal to their insertion points at the volar base of each finger’s middle phalanx (red dotted lines). This allows the flexor digitorum profundus (FDP) tendon to pass through the gap and insert on the volar base of the corresponding finger’s distal phalanx (joints labeled in blue). The FDS tendons are the first at risk with volar penetrating wounds involving the palm and proximal phalanges. The FDP tendon is particularly at risk with volar penetrating injuries of the middle and distal phalanges. Note the origin of synovial sheaths of the second digit (SS). B, Flexor pulley system. The pulleys are thickenings in the fibrous flexor sheath. There are five annular pulleys (transversely oriented fibers; A1 to A5). There are four cruciate pulleys (oblique, with some criss-crossing fibers; C1 to C4). The sheaths are tethered to the metacarpals and phalanges to create a pulley system and allow for up to 100 degrees of flexion at the PIP joint and 80 degrees at the DIP joint, as shown. (A courtesy Dr. D.A. Stearns, Department of Emergency Medicine, Massachusetts General Hospital, Harvard Medical School, Boston; B courtesy Kleinert Kutz Hand Care Center, Louisville, KY.)
Aspects of each digit. This complex of collateral vessels helps maintain perfusion of the hand when the radial or ulnar artery is compromised.

Arterial circulation can be assessed at the bedside. Tissue color, temperature, and distal capillary refill of the injured hand should be compared alongside the unaffected hand. The modified Allen test, although less sensitive than other noninvasive radiologic modalities, is an easy and rapid bedside maneuver to assess and compare the distal radial and ulnar arteries (see Fig. 43.21). After the examiner identifies the radial and ulnar pulses at the volar wrist, these are compressed, and the patient is asked to open and close the hand until the tissues are blanched from exsanguination. The examiner then releases one of the arteries, and vascular refill time is observed on the volar hand and digital tissue. The steps are repeated, and vascular refill is observed after release of the other artery. The refill times can be compared to each other, as well as to the unaffected hand. Each digit can be assessed in a similar fashion, because bilateral arterial injuries are at higher risk for poor outcome.²

Venous and Lymphatic Systems. Although the dorsal and superficial veins are numerous and varied in size and location, a common site for IV placement is the distal cephalic vein, located over the anatomic snuffbox and extending along the dorsum of the radius (see Fig. 43.11). The deep veins travel alongside the arteries, generally in a neurovascular bundle. The loose subcutaneous space on the dorsal hand contains much of the lymphatic system that drains next to the cephalic and basilic veins of the forearm, commonly resulting in dorsal swelling with hand infections.

Nerve Supply

Motor Innervation. The radial nerve (C6-C8 nerve roots) distribution on the hand and digits is entirely sensory (Fig. 43.22). The nerve passes from the brachial plexus into the posterior arm, where it divides into superficial and deep branches as it emerges from the radial groove at the elbow, between the brachialis muscle medially and brachioradialis muscle laterally.

Fig. 43.18. Each digit's muscle and tendon unit should be tested individually. A, The index finger flexor digitorum superficialis (FDS) tendon is checked by asking the patient to flex the corresponding proximal interphalangeal (PIP) joint while the adjacent digits are held in extension by the examiner. B, Finger flexor digitorum profundus (FDP) function is assessed by asking the patient to flex the distal interphalangeal (DIP) joints of each digit individually while the corresponding PIP joints are stabilized in extension by the examiner. C-E, The ring finger's flexor digitorum profundus (FDP), FDS, and lumbrical functions are tested individually. (Courtesy Dr. D.A. Stearns, Department of Emergency Medicine, Massachusetts General Hospital, Harvard Medical School, Boston.)
The deep branch supplies motor innervation to the dorsal forearm muscles (wrist-digital extensors, digital abductors, and forearm supinator). Motor function can be tested by asking the patient to extend the wrist, thumb, or digits against resistance and comparing the action to the opposite side.

The median nerve (C5-T1 nerve roots) originates from the lateral and medial cords of the brachial plexus and extends along the medial arm, crossing the elbow anteriorly and entering the forearm. It supplies all the anterior forearm muscle, with the exception of the flexor carpi ulnaris and ulnar aspect of the flexor digitorum profundus (fourth and fifth digits). As the nerve passes through the carpal tunnel and extends into the palm, the recurrent median nerve branches off and takes a superficial course along the surface of the thenar eminence, making it susceptible to injury from lacerations (Fig. 43.23; see Figs. 43.14). Recurrent median nerve function is tested by demonstrating thumb opposition—placing the tip of the thumb against the tip of the fifth digit (see Fig. 43.7). The median nerve extends distally and also supplies the index and middle finger lumbricals.

The ulnar nerve (C7-T1) originates from the medial cord of the brachial plexus and extends along the medial arm, crossing the elbow posteriorly to the medial humeral epicondyle before entering the volar forearm. It supplies the flexor carpi ulnaris and ulnar aspect of the flexor digitorum profundus (fourth and fifth digits).
The radial artery (RA) divides at the wrist sending a palmar branch over the palmar carpal ligament. Beyond the base of the thenar eminence it forms the superficial palmar arch (SPA) that contributes digital arteries (red stars). The artery sends a deep branch past the dorsum of the trapezium bone between the radial styloid process and the scaphoid bone, where it emerges within the anatomical snuffbox. It creates a dorsal carpal arch that parallels the extensor retinaculum. A deep branch passes into the palm between the first and second metacarpals to create the deep palmar arch. The ulnar artery's path (UA) enters into the palm by crossing over the flexor retinaculum in a space created by the pisiform bone and the palmar carpal ligament, also known as Guyon's canal. The artery forms a collateral with both the superficial and deep palmar arches. (Courtesy Dr. D.A. Stearns, Department of Emergency Medicine, Massachusetts General Hospital, Harvard Medical School, Boston.)

Sensory Distribution. The peripheral nerve supply to the hand and digits originate from the C5-T1 nerve roots that form the brachial plexus and its median, ulnar, and radial nerves. The terminal nerve patterns are important when examining a condition that appears to be isolated to the hand or digits, although overlap may occur along the borders of the classic distributions. The radial nerve is best tested at the first dorsal web space, median nerve at the fat pad of the index finger, and ulnar nerve at the little finger fat pad (Fig. 43.25).

Nerve damage in the setting of an acute injury may be difficult to assess. Sharp and dull testing results do not correlate well with subsequent findings at surgery; two-point discrimination is the test of choice in evaluating the hand and digits for sensory innervation. Two-point discrimination is not infallible, but consistent discrimination at a threshold distance comparable to the uninjured extremity makes significant nerve disruption unlikely. Significant variation from the uninjured hand, or threshold discrepancies wider than 5 mm on the fingertips, 1 cm on the palm, and 1.5 cm on the dorsum in the clinical context suggests sensory dysfunction. When there is doubt about whether innervation is intact, we recommend reexamination in 24 to 48 hours. Patients with hand injuries and subjective numbness or questionable two-point discrimination should receive an urgent referral and repeat evaluation within 1 week by a hand surgeon so that any nerve injury can be repaired within the required time window.

Fingertip

The fingertip is the portion of distal phalanx beyond the insertion of the flexor and extensor tendon insertions (Fig. 43.26). Adipose and fibrous connective tissue septa create the volar fat pad, containing sensory nerves and vascular collaterals from the digital neurovascular bundles.

Nail

This cornified epithelial plate takes origin from the nail root on the dorsum of the distal phalanx (see Fig. 43.26A and B). The
A–C, Wrist and palmar lacerations require an assessment of the arterial circulation. D, Arteriogram of the hand. The ulnar artery is the principal contributor to the superficial palmar arch. E–G, The Allen test can be used as a rapid assessment of radial and ulnar arterial integrity. E, After the examiner identifies the radial and ulnar pulses at the volar wrist, they are compressed, and the patient is asked to open and close the hand until the tissues are blanched from exsanguination. F, The examiner then releases one of the arteries, and vascular refill is observed on the volar hand and digital tissue. G, The steps are repeated, and vascular refill is observed after the other artery is released. The refill times can be compared to each other as well as to the unaffected hand. (A–C, E–G courtesy Dr. D.A. Stearns, Department of Emergency Medicine, Massachusetts General Hospital, Harvard Medical School, Boston; D courtesy Dr. D. Armstrong, Associate Professor of Radiology, University of Toronto, Ontario, Canada.)

A, B, Radial nerve (superficial branch; red stars) sensory distribution on the hand and digits proper is entirely sensory. The nerve emerges from under the brachioradialis tendon, passing over the anatomic snuffbox onto the hand dorsum. Note that the nerve branches several times at and beyond the anatomic snuffbox. The radial artery (RA) is identified within the anatomic snuffbox. C, Regional anesthesia of the radial nerve can be accomplished using ultrasound to identify the nerve two fingerbreadths proximal to the radial styloid process (cephalic vein, blue arrow; radial nerve, yellow arrow; brachioradialis tendon, red arrow). Care is taken to avoid injecting local anesthetic into the anatomic snuffbox because the distal RA passes through this area. (A, B courtesy Dr. D.A. Stearns, Department of Emergency Medicine, Massachusetts General Hospital, Harvard Medical School, Boston; C courtesy Dr. V. Noble, Department of Emergency Medicine, Massachusetts General Hospital, Harvard Medical School, Boston.)
Fig. 43.23. Median nerve (yellow stars) passing through the carpal tunnel into the hand palm. Note the superficial location of the recurrent median nerve (RMN) passing over the thenar eminence. Lacerations involving the thenar eminence require testing the integrity of this nerve, specifically through thumb opposition against the fingertips of the adjacent fingers (see Fig. 43.7). A, B, Regional anesthesia using ultrasound requires identification of landmarks adjacent to the median nerve. The radial artery pulse (RA), lies just lateral to the flexor carpi radialis (FCR) tendon. The flexor pollicis longus (FPL) tendon lies just posterior to the FCR tendon and just radial to the median nerve. The flexor digitorum superficialis (FDS) tendons are located just medial to the nerve (B, yellow arrow). The ulnar nerve (purple stars) lies just lateral to the flexor carpi ulnaris tendon (FCU) and joins the ulnar artery as it passes through Guyon’s canal, anterior to the carpal tunnel and lateral to the pisiform bone (green arrows). Note that the ulnar nerve divides proximally to the pisiform bone into dorsal and volar branches (purple arrows). (A courtesy Dr. D.A. Stearns, Department of Emergency Medicine, Massachusetts General Hospital, Harvard Medical School, Boston; B courtesy Dr. V. Noble, Department of Emergency Medicine, Massachusetts General Hospital, Harvard Medical School, Boston.)

proximal nail fold extends out over the proximal ends of the nail plate to form the eponychium (cuticle), perionychium (sides), and distal hyponychium. The nail plate, normally pink due to its highly vascularized matrix below, has a proximal white semicircular line called the lunula. The nail plate appears blue with peripheral vasoconstriction or cyanotic conditions. The entire length of the nail bed contributes to the growth and migration of the nail plate, approximately 0.5 to 1.2 mm/wk. If the nail bed is not repaired adequately, scarring will cause abnormal nail plate growth that can result in an irregular, split, or absent nail, which can be disfiguring.
**Fig. 43.26.** A, Surface anatomy of the nail. B–D, The fingertip. B, The fingertip consists of soft tissues beyond to the flexor and extensor tendon insertions on the distal phalanx. The nail consists of specialized epithelium containing keratin, extending over the dorsum of the phalanx. The nail root is covered by the proximal nail fold, which extends out over the proximal ends of the nail plate to form the eponychium and cuticle (yellow arrow), the sides with perionychium, and the distal end, the hyponychium (C). The nail plate grows distally from the nail matrix (M) and the nail bed (B to D, approximately 0.5–1.2 mm/ wk). C, The plate’s lunula (L) is a white semicircular line just distal to the nail fold. (A from Bope ET, Kellerman RD, editors: Diseases of the skin. In Conn’s current therapy 2015, Elsevier. pp 219–320, © 2015; B, D courtesy Dr. D.A. Stearns, Department of Emergency Medicine, Massachusetts General Hospital, Harvard Medical School, Boston; C from Siegel DB, Gelberman RH: Infections of the hand. Orthop Clin North Am 19:779–789, 1988.)

**CLINICAL FEATURES**

Providers should note patient age, hand dominance, occupation, medical conditions, previous hand ailments, medications, allergies, and tetanus immunization status. Identify the location of pain, swelling, discoloration, timing of onset of symptoms and their progression, aggravating and alleviating factors, current resultant functional disability, and previous history of similar symptoms and interventions. In cases of trauma, important information includes accurate time and circumstances surrounding the incident, mechanism, symptom progression, hand positioning at the time of injury, and any treatments prior to the
current evaluation. With amputation, elapsed time since the incident, and the location and care of the amputated part, are important factors.

The upper extremity, at least from the elbow down, should be examined to avoid concurrent or associated proximal conditions (Box 43.2). Evaluation should include a thorough assessment of vascular integrity, skin integrity, and neurologic function, followed by skeletal and joint stability and musculotendinous function. Tendinous injury or bony deformities may not be evident until the area is examined throughout its range of motion. Digital or regional anesthesia may be necessary to assess for fracture until the area is examined throughout its range of motion. Digital tendinous injury or bony deformities may not be evident until the area is examined throughout its range of motion. Digital or regional anesthesia may be necessary to assess for fracture stability, reduction, and stabilization adequately.

Assessment of open wounds requires knowledge of adjacent and underlying at-risk neurovascular, musculotendinous, and joint relationships. The emergency clinician will need adequate lighting, hemostasis, and the ability to compare tissues to the unaffected side. Wound length, depth, avulsion and tissue loss, flap viability, and contamination are should be considered when developing a management strategy.

**I. GENERAL APPEARANCE**
- A. Active hemorrhage
- B. Amputations or avulsions
- C. Position at rest

**II. SKIN**
- A. Integrity
- B. Moisture
- C. Swelling (edema, hematoma?)
- D. Discoloration
- E. Inflammation
- F. Scars

**III. VASCULAR**
- A. Color and warmth
- B. Pulses
- C. Capillary refill
- D. Allen test

**IV. NEUROLOGIC**
- A. Motor function
  1. Ulnar nerve—finger abduction and adduction
  2. Radial nerve—wrist extension
  3. Median nerve—flexion of digits 1, 2, and 3; thumb opposition
- B. Sensory function
  1. Ulnar nerve—volar tip of digit 5
  2. Median nerve—volar tip of digit 2
  3. Radial nerve—dorsum, first web space

**V. BONE AND JOINT**
- A. Deformity
- B. Local tenderness to palpation, passive range of motion
- C. Tenderness with axial compression
- D. Joint range of motion
- E. Ligamentous stability—distal interphalangeal, proximal interphalangeal, and metacarpophalangeal joints

**VI. MUSCULOTENDINOUS**
- A. Function of each muscle-tendon group
- B. Strength against resistance
- C. Tenderness with active motion

**DIAGNOSTIC TESTING**

Plain films are the most common and useful tools in the assessment of traumatic bony injury. In addition to posteroanterior, lateral, and oblique views, additional special views are used when seeking specific injuries. X-rays are obtained before and after closed fracture or joint reduction maneuvers.

Lacerations and puncture wounds with suspected retained foreign bodies, such as glass or metal, can be imaged with conventional radiography. Radiopaque materials are best seen with multi-view plain films. Less dense materials such as plastics or wood may not be seen on plain radiographs and are best evaluated with bedside ultrasound. However, emergency ultrasound may fail to identify foreign bodies smaller than 3 mm.

Computed tomography (CT) does not usually add significant information to conventional radiography in the trauma setting. CT scanning can show high resolution of the bony structures of the hand, but provides limited information regarding soft tissues such as muscles, tendons, and ligaments. CT may be helpful in the settings of complex, comminuted, or intraarticular fractures as well as highly suspicious clinical scenarios with the absence of fracture on plain films.

Magnetic resonance imaging (MRI) is rarely used in the evaluation of acute hand trauma. It provides visualization of soft tissues, including muscles tendons and ligaments, as well as the vascular system. It may be recommended as a follow-up modality to assess the carpal region and thumb more accurately when clinical suspicion is high for a complex avulsion fracture or ligamentous disruption.

**MANAGEMENT OF SPECIFIC INJURIES**

**Traumatic Injuries**

Due to the concentrated anatomy, a single mechanism of trauma can compromise multiple tissues. Lacerations (>50% of injuries) are the most common, followed by fractures (>10%). Prehospital management of hand injuries should focus on control of hemorrhage and pain control via splinting or analgesia. Amputated parts should be gently irrigated if contaminated and placed in a clean, dry, waterproof container on ice during transport.

**Fingertip Injuries**

The fingertip accounts for over 60% of hand injuries in children and 10% of job-related injuries. Fractures and soft tissue injuries occur with crush mechanisms, and shearing injuries can cause lacerations, tissue avulsions, and complex defects. Burns and frostbite can result in permanent tissue loss. Management goals of preserving neurovascularity and digital length will optimize function and recovery.

**Acute Nail Bed Injuries**

Approximately 50% of perionychial crush injuries result in distal phalangeal or tuft fractures. Radiographs should be obtained when bone involvement is suspected. Shearing forces can result in a concurrent laceration or significant tissue loss.

**Subungual Hematoma.** Nail bed compression may result in local hemorrhage contained between the nail folds and nail, causing a minimally swollen but highly pressurized, painful, and tender hematoma (Fig. 43.27). DIP extensor tendon function should be assessed and radiographs obtained for unstable fingertips. Trephination reduces pain, but does not hasten healing or alter infection risk, so it is generally used for large hematomas extending over more than 50% of the nail. Trephination is
accomplished using a heated, blunt-tipped needle device or disposable electrocautery unit to sear a hole through the nail, ensuring that pressure is light so that contact with the nail bed does not ensue. Multiple holes may be necessary to ensure adequate drainage. Alternatively, a hole can be drilled through the nail by the emergency clinician, who holds an 18-gauge needle by the hub, between the thumb and index finger, twirling it on its long axis rapidly and alternating direction. The bevel of the needle will drill a hole in the nail, avoiding the need for heat and the expense of electrocautery. Acrylic nails are potentially flammable and cautery is contraindicated. Concurrent distal phalangeal or ungual tuft fractures do not result in a difference in complications.

Traumatic subungual hematomas with nail disruptions or skin fold lacerations may have concurrent eponychial lacerations. Hematomas involving more than half the nail size have a 60% incidence of concurrent nail bed laceration, which increases to 95% if there is a distal phalanx fracture. When the nail and nail margins are intact, there is no significant difference in outcomes between nail trephination alone and formal nail bed repair, regardless of hematoma size. As a result, nail removal and repair of the nail bed is recommended only if the nail is broken or the nail edges are disrupted. Although the use of prophylactic antibiotics for open distal phalangeal fractures is controversial, we recommend managing grossly contaminated wounds or injuries in high-risk patients (e.g., those who are immunocompromised) with Cephalexin 250 mg qid or 500 mg bid (pediatric 25 to 50 mg/kg per day in 2 to 4 divided doses) for 3 to 5 days or until hand surgery follow-up. Clindamycin 300 mg tid (pediatric 8 to 12 mg/kg/day PO divided into 3 or 4 equal doses) may be used for penicillin-allergic patients. For patients not meeting these criteria, advice regarding signs of infection, combined with reevaluation in 72 hours and beyond, as needed, suffices. The nail may be lost but should regenerate with an intact germinal matrix.

**Nail Bed Lacerations.** Repair of nail bed lacerations is also controversial (see Fig. 43.27). Nail removal for eponychial repair is unnecessary except with significant disruption of the nail, skin folds, gross contamination, or when the eponychium–nail matrix area is involved. Primary repair using interrupted 5-0 or 6-0 absorbable sutures minimizes subsequent nail deformity and reduces functional disability. Late reapproximation yields unpredictable results (see Fig. 43.27). The original nail can be used to splint and protect the healing eponychium, replaced into the nail fold and secured using sutures. (Courtesy Dr. D.A. Stearns, Department of Emergency Medicine, Massachusetts General Hospital, Harvard Medical School, Boston.)
defects are best managed by securing the nail onto the original avulsion site using through and through sutures at the edges.

Foreign Bodies in the Hand

Depending on their cause, penetrating wounds often have retained foreign bodies. A detailed history of how the injury occurred will help identify the likelihood of a foreign body. Wood splinters, in particular, are notorious for breaking off during the penetration or removal attempts. Penetration or laceration by broken glass similarly has a high incidence of a retained foreign body. Other materials include metal, sand particles, and organic materials, such as soil, grease, or paint. Suspicious clinical clues include sharp localized tenderness with wound palpation or manipulation, a palpable mass, or persistent draining wounds.

Radiographs and bedside ultrasound are useful for locating foreign material. However, small objects (<3 mm diameter) are difficult to detect by either modality. If there is strong suspicion of a foreign body despite negative plain films, and the wound is not amenable to exploration, a CT or MRI scan is obtained. MRI should not be used if the foreign body is metallic. Imaging is not required if the suspicion for retained foreign body is low, and plain radiographs and bedside ultrasound are negative. Similarly, further imaging is not required if the entire length and depth of the tissue defect can be visualized. When suspicion is low for a foreign body and advanced imaging is not performed, the patient is advised regarding follow-up for persistent pain, poor wound healing, or signs of infection within the first 7 days of injury.

In general, foreign bodies in the hand are best managed by removal in the emergency department (ED) or in the operating room. The exception is very small (≤3 mm) foreign bodies of an inert material (eg, glass, metal) that located where their continued presence likely carries a smaller risk of long-term problems than the tissue disruption from the removal procedure. Objects not requiring removal include small, inert foreign bodies not in close proximity to a joint, tendon, nerve, or vessel, objects that are unlikely to migrate into vital structures or the circulation, and those without tenderness on examination. The emergency clinician should explain to the patient why the dangers of removal outweigh the benefits. Indications for removal of foreign bodies include pain and tenderness limiting function, risk of systemic toxicity (eg, from lead), risk of infection, including deep space infection (eg, from wood, soil, contaminated material), and immediate risk to adjacent vital structures. Foreign bodies related to marine envenomation are discussed in Chapter 55. A superficial object that can be identified by gentle probing (eg, with a hemostat) or seen with minor exploration is removed in the ED. Deep wounds at risk for concurrent tendon, neurovascular, or joint injury will require hand surgery consultation for removal in the operating room (Box 43.3).

If the foreign body is small, not strategically located, and noncontaminated, and therefore does not require immediate removal, referral to a hand surgeon within 72 hours for further evaluation and possible delayed exploration is advised. The patient should be informed of the specific follow-up arrangements and indications for immediate return to the ED. If there is minimal or no evidence of concurrent contamination, the wound can be irrigated and closed primarily. As with other wounds, tetanus prophylaxis is administered following Centers for Disease Control and Prevention guidelines (see Chapter 52.) There is no high-quality evidence that antibiotic administration reduces infection in those in whom a foreign body is retained or has been removed. We recommend daily wound checks for 3 days to ensure that there is no evolving infection. If infection occurs, treatment consists of Cephalexin 250 mg qid or 500 mg bid (pediatric 25 to 50 mg/kg per day in 2 to 4 divided doses) for 7 days or until hand surgery follow-up. Clindamycin 300 mg tid (pediatric 8 to 12 mg/kg/day PO divided into 3 or 4 equal doses) may be used for penicillin-allergic patients.

Hand Fractures

Principles

The bones of the hand are the most commonly fractured bones in the entire body. The mechanism of injury often determines the nature of the fracture; direct blunt trauma is more likely to cause a transverse or comminuted fracture, whereas a twisting mechanism or axial loading is more likely to result in an oblique or spiral fracture. Associated injuries may include nerve, vascular, tendinous, and ligamentous injuries. Hand fractures are classified according to site and type of fracture, alignment, and whether the fracture is closed or open.

Transverse fractures are stable, although spiral, oblique, and comminuted fractures and fractures associated with dislocations are considered unstable. Most closed injuries can be managed in the ED with appropriate splinting, but unstable, open, intraarticular, and periarticular fractures usually require operative management. Reduction and splinting of fractures and dislocations is an essential management principal (Fig. 43.28). The duration of splinting should be no longer than necessary to avoid loss of mobility and flexibility. In general, splinting is done with the hand in the universal safe or functional position. In this position, the wrist is extended 15 to 30 degrees, the thumb is extended and abducted, with the other fingers in a relaxed position of 60 degrees of flexion at the MCP, and minimal flexion (5–10 degrees) at the PIP and DIP joints. This position minimizes shortening of tendons and ligaments, and thus stiffness, during the splinting duration.

Clinical Features

Distal Phalanx Fractures. Fractures of the distal phalanx are the most common fractures of the hand and are frequently complicated by nail injuries. Fractures may be to the tuft, shaft, or base. Distal and tuft fractures can be quite painful because of soft tissue swelling in the highly innervated finger pad.

Fractures at the base of the distal phalanx often are caused by tendon avulsion. Avulsion injuries can be diagnosed clinically by local tenderness over the avulsion site and the inability to move the joint actively. Avulsion fractures are easily identifiable on plain radiographs.

Management. Tuft fractures heal without incident. Most distal phalangeal fractures are stable and nondisplaced and can be managed conservatively with elevation, analgesia, wound care for
Splints
Which to Consider and When?

Forearm Volar “Cockup” Splint
Soft tissue hand/wrist injuries
Most wrist, 2nd-5th metacarpal fractures (for transport)
Sandwich splint add a dorsal slab stability
Not for distal radius or ulnar fractures–forearm supination/pronation still possible!

Burkhalter:
Metacarpal neck fractures, MCP dislocations
Volar slab 30 degrees wrist extension
Dorsal slab with 90 degrees metacarpal flexion

Forearm Sugar Tong:
Distal radius and ulnar fracture
Prevents forearm pronation/supination

Thumb Spica:
Scaphoid, thumb MCP
De Quervain tenosynovitis
Wine glass position immobilization of 1st MCP
Allows thumb DIP free to oppose

Functional position = neutral position = “beer can” position
Wrist extension, (10-25°) digits resting flexion
Metacarpal neck fractures: MCP joint flexed to 90°
Thumb fracture: abduction, flexion “wine glass”

Ulnar Gutter:
4th-5th metacarpal, MCP joint,
Prox/Middle
P = phalangeal sprains/fractures

Radial Gutter:
Sprains/fractures
2nd-3rd digital metacarpal, MCP Joint,
Proximal middle phalanges

Finger Splints:
Stable middle, distal phalanx fractures
PIP sprains: dynamic splint (buddy taping)

Fig. 43.28. Hand—digital splints. A forearm volar cockup splint in resting, functional position is considered for temporary immobilization of soft tissue injuries, including tendon and neurovascular tissues, as well as minimally displaced metacarpal fracture. A dorsal slab may be added for improved stability. The wrist joint will remain capable of pronation and supination; hence, additional immobilization should be considered for concurrent injury. A Burkhalter splint includes a volar slab immobilizing the wrist at 30 degrees of extension and a dorsal slab crossing the metacarpophalangeal (MCP) joint to ensure 90 degrees of MCP flexion, allowing for improved stabilization and alignment of metacarpal fractures and MCP joint dislocations. A forearm sugar tong splint should be added when concurrent wrist injuries exist and the risk of a pronation-supination motion may create further complications. Thumb spica splint immobilization is indicated with the risk of a distal radius, scaphoid-first metacarpal and first MCP joint injury; splint immobilization includes 30 degrees of wrist extension and resting position of the first MCP. The thumb distal interphalangeal (DIP) joint is open and allowed to maintain opposition. An ulnar gutter is considered for minimally displaced fourth and fifth metacarpal joint, MCP joint, and proximal and middle phalangeal injuries. The wrist is immobilized in extension, with the digits in resting, intrinsic-plus positioning. Digital splinting is considered for stable stable middle distal phalangeal fractures and proximal interphalangeal (PIP) joint strains. (Courtesy Dr. D.A. Stearns, Department of Emergency Medicine, Massachusetts General Hospital, Harvard Medical School, Boston.)

soft tissue injuries (if present), and splinting. Nondisplaced distal phalangeal shaft fractures may be splinted in extension, using a simple distal phalangeal joint splint (leaving the PIP joint fully mobile) for 2 to 3 weeks for protection and comfort. Fractures with angulation, rotation, or displacement may require closed reduction under digital or metacarpal nerve block anesthesia, followed by volar splinting. Irreducible and open fractures require hand surgery consultation.

Avulsion-type fractures are managed like other closed tendon injuries, with splinting to reduce the tension on the fracture and referral to a hand surgeon for possible repair. Flexor tendon avulsion fractures (ie, the so-called Jersey finger because of the association with tackling sports) involving the flexor digitorum profundus require surgical repair. Mallet finger is the term applied to extensor avulsion fractures, but also may be caused by distal extensor tendon ruptures (Fig. 43.29). The injuries are be splinted in full extension (typically, 0–10 degrees extension) at the DIP joint for 6 to 8 weeks, followed by part-time splinting for an additional 4 to 6 weeks. We recommend hand surgery consultation within 7 days because some of these injuries require surgery.
Fractures distal Index, inability (DIP) the joint include Ring, actively. to extend Examination may reveal local swelling, bony
Clinical forced local common Mallet Middle, Fingers. DIP characteristics mechanism and joint during interphalangeal flexion A, B, is angulation. Therefore, fractures at the neck of the middle insert on the proximal portion of the dorsal base (see Figs. 43.13, the volar surface of the phalanx, and the extensor tendon, which digitorum superficialis, which divides and inserts along much of phalanx has two important tendon insertion sites, the flexor and radial styloid process.

gently closed fist (except the thumb) should point to the scaphoid when the fingers are loosely flexed, the nails of the digits should at rest and with motion of the MCP and PIP joints. Normally, when the fingers are loosely flexed, the nails of the digits should lie in the same parallel plane (Fig. 43.30), and all the fingers of a gently closed fist (except the thumb) should point to the scaphoid and radial styloid process.

Fracture alignment may be assessed clinically by comparing the injured digit to the unaffected hand or adjacent normal fingers at rest and with motion of the MCP and PIP joints. Normally, when the fingers are loosely flexed, the nails of the digits should lie in the same parallel plane (Fig. 43.30), and all the fingers of a gently closed fist (except the thumb) should point to the scaphoid and radial styloid process.

Management. ED management includes appropriate analgesia, fracture reduction when necessary, splinting, and consultation with a hand surgeon, as needed.

Phalangeal fractures need precise anatomic alignment for good results. However, most fractures are nondisplaced and can be managed with dynamic splinting by “buddy-taping” to an adjacent finger for early protected motion (see Fig. 43.28). This allows for fracture healing and reduced stiffness. Management of unstable or displaced fractures depends on the ability to obtain closed reduction and anatomic alignment. Reducible fractures can be immobilized with gutter or anteroposterior (Burkhalter) splints. Spiral, oblique, comminuted, intraarticular, and nonreducible fractures should have a hand service consultation for possible open reduction and fixation.

Complications. Malunion, malrotation, and proximal phalangeal volar angulation may occur, requiring hand specialist consultation and referral for definitive operative management.

Metacarpal Fractures. Metacarpal fractures are common, representing one-third to one-half of all hand fractures. Most injuries occur in male patients who have sustained the injury from punching with the dominant hand in a clenched fist. Falls are the most common mechanism for patients younger than 9 and older than 50 years. Important information for definitive management includes mechanism of injury, open versus closed condition, fracture stability, and reducibility.

Due to the need for functional mobility, the thumb, index, and middle fingers have little tolerance for deformity as compared to the ring and little fingers. Carpometacarpal (CMC) joint range of motion decreases across the cascade of digits from the thumb to little finger. The thumb, index, and middle fingers can accommodate far less degree of dorsal angulation (10–15 degrees) and still retain adequate function when fractured compared to the ring (40–45 degrees) and fifth digit (50–70 degrees). Rotational deformities are poorly tolerated by all digits. Except for simple boxer’s fractures (see below), all metacarpal fractures should receive consultation or referral to a hand surgeon as part of the management plan.

Metacarpal Fractures of the Index, Middle, Ring, and Little Fingers. Examination may reveal local swelling, bony
deformity, and tenderness to palpation or axial compression. Suspicious dorsal wounds should be considered as being caused by a fight bite and managed accordingly. Fourth and fifth metacarpal fractures may injure the ulnar nerve, causing intrinsic hand muscle weakness and digital numbness. Plain radiographs will reveal most fractures. CT imaging can assess displacement of intraarticular fractures.

The metacarpal neck is the most common fracture location, typically incurred from direct impaction resulting in dorsal angulation. A so-called boxer’s fracture—metacarpal neck fracture of the fifth digit—is the most common type (see Fig. 43.30). The physical examination commonly reveals tenderness, with or without deformity. Metacarpal shaft fractures, usually from axial trauma, may be transverse or comminuted and cause dorsal angulation. Oblique and spiral fractures usually result from rotational torque and tend to shorten or rotate the digit (see Fig. 43.30). Less common injuries include the metacarpal head, caused by direct blunt trauma or crush injury, and metacarpal base, caused by torsion and associated with carpal bone injuries.

**Management.** Management of most stable, nondisplaced metacarpal fractures consists of reduction and splinting in the intrinsic-plus position, with the wrist extended 30 degrees, the
Fractures
Due to increased anxiety, and personality disorders and are at risk for recurrent and neck have been shown to have higher rates of violent behavior, stiffness may occur. Patients with fractures of the metacarpal head and fixation.

Metacarpal base fractures commonly involve the carpometacarpal articulation, resulting in an intraarticular fracture or joint displacement. Because they frequently remain angulated and displaced with closed reduction alone, we recommend referral for definitive operative management by a hand surgeon.

Metacarpal shaft fractures may be reduced after adequate anesthesia with a hematoma or regional block. Goals of treatment include, less than 3 mm of metacarpal shortening, less than 10 degrees dorsal angulation for the index and middle fingers, less than 20 degrees for the ring and little fingers and elimination of a shaft rotational deformity. The 90-90 reduction method includes having the MCP, PIP, and DIP joints flexed to 90 degrees and application of dorsal pressure over the fracture, with immobilization in the intrinsic-plus position (see above). However, if reduction of dorsal angulation cannot be obtained, proper metacarpal length is not maintained, or digital malrotation is present, operative stabilization is necessary.

Metacarpal neck fractures, including the boxer’s fracture, are commonly managed nonoperatively. Reduction goals for displaced metacarpal neck fractures is controversial. Consensus is that there should be less than a 15-degree angulation for the index or middle finger, up to 35 degrees for the ring finger, and 45 degrees for the fifth digit (acceptable ranges of 20–70 degrees from the second to fifth digits have been quoted). These fractures may be reduced using the 90-90 method with intrinsic-plus splint positioning. Malrotation and persistent angulation, despite reduction attempts are indications, for surgical intervention.

Metacarpal head fractures may be intraarticular and comminuted, with a high risk of fracture displacement and malrotation. These are best managed using intrinsic-plus or gutter splint immobilization and immediate hand service referral for operative repair.

Lacerations or puncture wounds over the MCP joint associated with fractures should be considered open and highly contaminated, requiring antibiotics and consultation with a hand surgeon for consideration of operative debridement, irrigation, and reduction.

Complications. Avascular necrosis, nonunion, misalignment, intersosseous muscle or tendon injury or fibrosis, and chronic stiffness may occur. Patients with fractures of the metacarpal head and neck have been shown to have higher rates of violent behavior, anxiety, and personality disorders and are at risk for recurrent injury. Prevention strategies and/or psychiatric screening should be considered.

Metacarpal Fractures of the Thumb. Due to increased digital mobility, thumb metacarpal fractures are less common than finger metacarpals. Most fractures involve the base and are classified as extraarticular or intraarticular. Extraarticular fractures are more common and usually result from direct trauma or impaction. They may be transverse, oblique, and epiphyseal (in children). Examination may reveal thenar eminence swelling and ecchymosis. Transverse fractures are usually stable and can be managed with closed reduction and immobilization. Fractures of more than 30 degrees of angulation should undergo closed reduction and immobilized in abduction, with the IP joint extended in a thumb spica splint. Oblique extraarticular fractures are generally unstable, requiring hand service consultation for open reduction and fixation.

Bennett and Rolando fractures are two intraarticular fractures of the thumb base resulting from an axial force acting on a partially flexed metacarpal (Fig. 43.31). The more common Bennett fracture involves an intraarticular metacarpal base fracture combined with first CMC ligamentous disruption, causing dislocation or subluxation of the distal metacarpal shaft. The larger fragment is subluxed dorsally by the force of the abductor pollicis longus muscle, whereas the ulnar portion remains in place. Management includes reduction of the fracture dislocation and immobilization in a thumb spica splint, with outpatient hand service follow-up. In a Rolando fracture, the thumb metacarpal is comminute, and thus carries a worse prognosis than the Bennett fracture. Although at times difficult to see on plain films, the classic radiographic Y- or T-shaped pattern is a typical configuration of comminution. Management includes thumb spica splint immobilization and hand service consultation for early follow up. Definitive treatment is controversial and depends on the severity of comminution at the base of the thumb and degree of displacement. Malunion is the most common late complication of metacarpal thumb fractures, followed by posttraumatic arthritis. Nonunion is rare.

Soft Tissue Injuries

Soft tissue injuries of the hand can result in disabling musculotendinous, neurovascular, and joint compromise, local and deep space infection, and retained foreign bodies. Standard principles of wound management including irrigation, exploration, removal of foreign material, débridement when necessary, consideration of primary versus delayed closure, and appropriate antibiotic prophylaxis. Closure of skin defects should be based on injury mechanism, wound age, size and location, degree of contamination, functional implications, and patient comorbidity.

High-risk injuries that should receive antibiotic prophylaxis include bites, puncture or avulsion wounds (with or without musculotendinous injury), injuries that penetrate a joint, bony or neurovascular involvement, and wounds with contaminated or devitalized tissue. Immune deficiency (eg, diabetes mellitus) should also direct therapy. When clinically indicated, tetanus and rabies prophylaxis should be provided (see Chapters 52 and 123).

Dislocations and Ligamentous Injuries

Principles

Injured dorsal, collateral, or volar plate ligaments may be focally tender when palpated. Ligamentous injuries are classified as stretching with small tears (grade I), incomplete partial tears (grade II), or complete tears (grade III). With incomplete joint dislocation (ie, subluxation), the articular surfaces are only partially separated. A dislocation is complete when articular surfaces are completely separated.

Accurate assessment of joint stability includes testing passive and active ranges of motion. After a neurologic assessment, local or regional anesthesia may be needed to assist with the examination, because testing motor function may be limited by pain. The affected joint should be examined using passive range of motion to assess for stability. Full range assessment on the affected joint should include radial–ulnar and dorsal–volar stress in an extended and semi-flexed joint position to evaluate collateral and volar plate stability, respectively. Active stability can be evaluated by asking the patient to range the affected joint. Limitation of full range of motion or joint displacement suggests instability. The joint can be compared to that of the adjacent digit, as well as that of the unaffected hand. Plain and stress radiographs of the joint may confirm instability.

Adjacent soft tissues in grades I and II partial ligamentous injuries are commonly swollen, yet the joint remains stable with stressing, passive, and active motion. Stable joints are less likely to require surgical repair. Grade III complete ligamentous injuries
will be unstable during ranging and exhibit wide displacement on stress testing.

**Interphalangeal Joint Injuries**

**Distal Interphalangeal Joint**

Collateral and volar ligaments, as well as the flexor and extensor tendons, stabilize the DIP joint. For this reason, DIP dislocations about this joint are less common, often associated with open wounds. Prior to joint reduction, radiographs should be obtained to identify intraarticular or avulsion injuries. Local or regional anesthesia may be required. Dorsal pressure, combined with longitudinal and hyperextended traction, should be used to secure the joint, followed by splinting in the functional position. Avulsion fractures, volar plate tears, or tendon entrapment may prevent reduction and require operative repair. Open dislocations are managed with wound care, skin closure, splint immobilization, prophylactic antibiotics, and hand service referral.

**Proximal Interphalangeal Joint**

The proximal interphalangeal (PIP) joint is the most common joint dislocated in the hand. Although the extensor central slip provides additional dorsal stability as it inserts on the base of the middle phalanx, loading mechanisms may cause complete disruption of more than one ligament, resulting in middle phalangeal dislocation.

PIP dislocations are named for the direction of displacement of the middle phalanx. Dorsal dislocations without fracture, caused by hyperextension, are the most common. A volar plate fracture at the base of the middle phalanx may also occur (Fig. 43.32). Fractures involving more than 50% of the joint surface are unstable and often require surgical repair. Lateral radial or ulnar forces may rupture collateral volar ligaments, with a sixfold greater incidence of radial collateral rupture resulting in ulnar deviated dislocations. Rotational longitudinal compression of the middle phalanx may result in volar plate and collateral disruption. Such volar dislocations are uncommon, difficult to reduce, and may be

---

**Fig. 43.31.** First metacarpal base fractures. A, B, Bennett fracture (1882), an oblique intraarticular fracture of the base of the first metacarpal. A triangular-shaped fragment rests at the medial (ulnar) base of the metacarpal, held in place by multiple ligaments between the fragment and trapezium; the remaining metacarpal bone is displaced dorsally and laterally (radially) from the abductor pollicis muscle. C, D, Rolando fracture (1910), a comminuted intraarticular fracture of the first metacarpal base involving at least three fragments, typically forming a Y or T configuration. D, Comminuted intraarticular fracture, a worse prognosis than a Bennett fracture. This requires prompt immobilization and referral for best outcome. (Courtesy of Dr. L. Avery, Department of Radiology, Massachusetts General Hospital, Harvard Medical School, Boston.)
some contribution from the extensor and flexor tendons insertions provide stability. Dorsal dislocations are most common. Dislocations should be reduced using digital nerve anesthesia, followed by splinting in the functional position in 2 to 3 weeks.

**Metacarpophalangeal Joint Injury**

The more condyloid shape of the MCP joint allows for abduction, adduction, flexion, and extension. Collateral and volar ligaments stabilize deep and superficial transverse metacarpal ligaments, which in turn stabilize the joint. The joint becomes more stable in a flexed position as the collateral ligaments are stretched across the articulation. MCP joints are most vulnerable to dorsal and lateral distracting forces; the most common dislocations are from hyperextension injuries. Simple dislocations are often subluxed, with the joint resting in at least 60 degrees of hyperextension, with tender, ecchymotic swelling. Complex dislocations are complete disarticulations; they are unstable, yet often appear less angulated than simple injuries. In addition to tender ecchymotic swelling, a palpable, displaced, metacarpal head dimples the palm. An interposed volar plate or sesamoid bone may prevent reduction. The Brewerton view (fingers flat on the radiograph plate, MCP joints flexed 65 degrees, and the beam angled from a point 15 degrees to the ulnar side of the hand) can identify concurrent bony injury.

**Management.** Hyperextension and longitudinal traction should be avoided because the volar plate of the MCP joint may become entrapped in the joint space. Rather, simple subluxed MCP joints should be reduced with the wrist in flexion, relaxing the flexor tendons, and applying direct dorsal pressure on the associated with central slip extensor tendon detachment, leading to a boutonnière deformity (see Fig 43.13).

**Management.** Radiographs can identify the type of dislocation, as well as associated fractures. Management should balance the importance of early motion to prevent long-term stiffness with the need to protect unstable injuries. Fractures involving more than one-third of the intraarticular surface commonly require surgical correction. Smaller fractures do not always require repair and may improve with 2 to 3 weeks of immobilization, followed by progressive range of motion. Reduction of dorsal and lateral PIP joint dislocation is accomplished using longitudinal traction and PIP hyperextension, followed by dorsal pressure on the proximal middle phalanx. Some volar dislocations may reduce successfully using longitudinal traction, with the MCP and DIP joints flexed. However, definitive management is controversial, and many will require open reduction.

Dorsal and lateral dislocations should be immobilized in 20 to 30 degrees of flexion or with an extension block splint—dorsal splint allowing flexion but restricting extension—for 2 to 3 weeks, followed by active movement. Reduced volar dislocations should be splinted in full extension. Open or irreducible dislocations, unstable reductions, dislocations with volar plate avulsion and intraarticular fractures involving more than 30% of the joint surface should receive hand service referral.

**Injury to the Interphalangeal Joint of the Thumb**

Thumb phalanges are stronger, but otherwise the joint is similar to a finger DIP joint. The collateral ligaments, volar plate, and...
prolonged forceful abduction of the MCP joint, resulting in ligamentous injury at its insertion onto the proximal phalanx. The injury may be associated with an avulsion fracture and result in a complete or incomplete ligament tear (Fig. 43.33). Inadequate management and repeat injury may result in chronic disability. Skiing has become the most common cause of acute and chronic injury to the UCL. A Stener lesion occurs when the superficial portion of the ligament is drawn proximally. Ulnar deviation of the MCP joint allows the adductor pollicis tendon to interpose between the superficial and deep distal portion of the UCL ligament, resulting in improper healing in up to two-thirds of cases. Concurrent volar plate and joint capsule injuries may occur. Examination reveals swelling over the MCP joint and thenar eminence, with particular tenderness over the ulnar portion of the joint, as well as pain and weakness of thumb pinch. Valgus stress on the affected UCL, by applying a radial stabilizing force while gently abducting the joint, assists in diagnosis. UCL laxity (15 degrees > the unaffected thumb or >35 degrees overall) suggests a complete UCL rupture. Because this diagnostic maneuver can lead to a Stener lesion, it should only be performed after radiographs are obtained to exclude a concurrent avulsion fracture.

Management. Partial UCL injuries may be managed with thumb spica immobilization and outpatient hand service referral. Surgical repair within 3 weeks of injury will result in good to excellent recovery in 90% of patients with Stener lesions or complete ligament rupture.

Radial Collateral Ligament Injuries.

A radial collateral ligament injury is caused by forced adduction. It is tenfold less common than an UCL injury, but can be equally debilitating, with loss of pinch strength and chronic pain. Management strategy is similar to that for UCL injuries, including a careful history, radiographs, varus stress testing, thumb spica immobilization, and hand service referral.

Tendon Injuries

Lacerations and puncture wounds, as well as crush and forced hyperextension, may result in a range of tendon injuries, including strain, complete rupture, and avulsion fracture. At rest, the balance of forces between digital flexors and extensor musculature results in a semiflexed or functional position, with a progressively greater degree of flexion from the index to the fifth fingers. If active ranging is present, but elicits discomfort along the tendon, a partial tear may exist. An injured finger with a greater or lesser degree of resting flexion when compared to adjacent digits, as well as that of the opposite hand, may indicate a tendon injury (Fig. 43.34). Meticulous, individual tendon function should be tested for motion against resistance. Initiating the test at maximal tendon stretch creates the greatest contraction strength for motion against resistance and can be compared to adjacent and opposite tendon function. Shorn tendons may retract proximally or distally into a wound, depending on hand positioning at the time of injury (eg, grasping versus extended). Thus, all tendons should be inspected throughout their entire range of motion during wound exploration.

Extensor Tendon Injuries

Principles. Lack of fibrous tendon sheaths and minimal amount of protective subcutaneous tissue make the extensor tendons over the hand dorsum prone to injury. The timing of definitive repair is controversial, but should generally be within 2 weeks of injury. Extensor tendon injuries have been grouped according to anatomic zones for assessing injury, consideration of repair techniques, and rehabilitation. Eight zones of tendon
The extensor tendon’s central and Harvard cadaver Hospital, degree Emergency Stearns, Avery, Boston; Dr. This zone includes the conjoined General Department of on Medical of MCP specimen Compare E, the L. General (defect Department B, C Gamekeeper’s Massachusetts Hospital, The second most common sports-Radiology, Harvard). Zone III Extensor Injuries. The extensor tendon’s central and lateral bands pass over the middle phalanx in this region. The central band inserts on the middle phalanx and the lateral bands extend to the base of the distal phalanx. Rarely, lacerations transecting all the tendons will produce a mallet deformity. Treatment options are similar to those for zone I injuries.

Zone II Extensor Injuries. The extensor tendon’s central and lateral bands pass over the middle phalanx in this region. The central band inserts on the middle phalanx and the lateral bands extend to the base of the distal phalanx. Rarely, lacerations transecting all the tendons will produce a mallet deformity. Treatment options are similar to those for zone I injuries.

Clinical Features and Management

Zone I Extensor Injuries. This zone includes the conjoined extensor tendon over the DIP joint and its insertion at the dorsal distal phalanx. Partial tendon injuries may present with extension lag, with reduced strength on resistance testing. Complete transection of the tendon from open or closed trauma results in an unopposed flexed posture at the DIP joint.

Mallet finger, caused by forced flexion of the extended finger, is the most common sports-related tendon injury (see Fig. 43.29). Up to one-third of mallet fingers have associated avulsion fractures. The DIP joint may be held in flexion at rest, with dorsal swelling and tenderness. Closed injuries benefit from early immobilization in extension, allowing PIP and MCP joint mobility. Most will improve within 6 to 8 weeks of immobilization. Open injuries, with partial or complete tendon laceration, are typically closed using 5-0 nonabsorbable sutures and the DIP joint splinted in extension for 6 to 8 weeks. Patients with chronic untreated mallet fingers may develop swan neck deformities from dorsally displaced lateral bands causing PIP joint hyperextension (Fig. 43.36).

Trajectory have been defined, from the distal digit to the proximal forearm (Fig. 43.35; see Fig. 43.13). Partial and compete lacerations are repaired with a roll suture or figure-of-eight stitch with 5-0 nonabsorbable sutures (for zones I–IV) or 4-0 nonabsorbable sutures (for zone V and higher). Repair typically is performed by a hand surgeon, but may be done by the emergency clinician if properly trained, with follow-up by a hand surgeon.

Simple, clean tendon lacerations may be repaired in the ED if partial-thickness or full-thickness, with both ends easily visualized. However, because extensor tendon injuries are prone to functional impairment if not precisely repaired, and because structures are difficult to visualize without magnification and wound extension, we recommend that all injuries other than those easily visualized in zone VI be referred to a hand specialist by an urgent (1–3 day) follow-up appointment. Prior to discharge, wounds should be thoroughly irrigated and the patient started on prophylactic antibiotics covering skin flora.

Clinical Features and Management

Zone II Extensor Injuries. This zone includes the conjoined extensor tendon over the DIP joint and its insertion at the dorsal distal phalanx. Partial tendon injuries may present with extension lag, with reduced strength on resistance testing. Complete transection of the tendon from open or closed trauma results in an unopposed flexed posture at the DIP joint.

Mallet finger, caused by forced flexion of the extended finger, is the most common sports-related tendon injury (see Fig. 43.29). Up to one-third of mallet fingers have associated avulsion fractures. The DIP joint may be held in flexion at rest, with dorsal swelling and tenderness. Closed injuries benefit from early immobilization in extension, allowing PIP and MCP joint mobility. Most will improve within 6 to 8 weeks of immobilization. Open injuries, with partial or complete tendon laceration, are typically closed using 5-0 nonabsorbable sutures and the DIP joint splinted in extension for 6 to 8 weeks. Patients with chronic untreated mallet fingers may develop swan neck deformities from dorsally displaced lateral bands causing PIP joint hyperextension (Fig. 43.36).
can be repaired using 5-0 nonabsorbable sutures, followed by immobilization in a functional position.

Zone V Extensor Injuries. These injuries commonly involve the flexed finger MCP joints. Clenched fist injuries can be closed or open. Radiographs should be obtained to rule out metacarpal head and articular fractures. The inability to extend the MCP joint fully, with local swelling and tenderness, suggests tendon injury. Unless proven otherwise, all open injuries over the MCP joint should be presumed secondary to a punch to the mouth or fight bite. A misleading history or innocuous wound appearance should not dissuade the examiner from making this diagnosis, because risk of infection is high and should be treated expeditiously with antibiotics and possible operative washout. Wounds should be left open, and patients should receive empirical antibiotics to cover Staphylococcus aureus, streptococci, Eikenella corrodens and anaerobes. We recommend the combination of a β-lactam and β-lactamase inhibitor such as amoxicillin-clavulanate, 875/125 mg (25 to 30 mg/kg/day) orally bid for 3 to 5 days or until hand surgery follow-up. For penicillin-allergic patients, clindamycin, 300 mg (8 to 12 mg/kg/day) tid, plus double-strength trimethoprim-sulfamethoxazole (8 to 10 mg/kg/day) bid, doxycycline, 100 mg passes dorsally over the PIP joint. Causes of closed injuries include forced flexion and extension and crush to the dorsum of the PIP joint. At this level, lacerations may involve the tendon and the joint, warranting careful wound examination through a full range of motion. A boutonnière deformity may result from damage and displacement of the extensor hood, as well as the attachments of the central tendon’s lateral bands causing volar displacement and resulting in a paradoxical PIP joint flexion and DIP joint hyperextension (see Fig. 43.13). Diagnosis should be suspected with PIP joint swelling in flexion with concurrent DIP joint extension and tenderness along the tendon. The Elson test may identify a central slip rupture; with the patient’s PIP joint in 90 degrees of flexion over the edge of a counter, the patient is asked to extend the middle phalanx actively. Weak extension with rigid DIP joint extension is suggestive of a central slip injury (Fig. 43.37). Closed PIP joint injuries should be immobilized in extension, leaving the DIP joint free, with referral to a hand specialist. Patients with open injuries should receive prophylactic antibiotics, tetanus, and immediate hand service consultation.

Zone IV Extensor Injuries. Partial and complete tendon injuries over the proximal phalanx do not retract appreciably and can be repaired using 5-0 nonabsorbable sutures, followed by immobilization in a functional position.
CHAPTER 43 Hand

Zone VII and VIII Extensor Injuries. These tendon injuries involve the wrist and forearm and should be referred to hand service consultation for definitive management.

Flexor Tendon Injuries

Principles. Flexor tendon injuries of the hand are less common than extensor tendon injuries. The most common closed flexor tendon injury of the hand is an FDP tendon avulsion from the forceful extension of a flexed digit. The digit may rest in relative extension due to unopposed extensor function. Isolated joint function testing of should assess individual FDP, FDS, and lumbrical function. The volar hand is divided into five anatomic zones to assist with defining areas of injury and potential tissue involvement (Fig. 43.38).

Flexor tendon injuries are more difficult to treat than extensor tendon injuries and should be referred for hand specialist consultation. The intricacy of the hand's volar anatomy has given it the nickname of “no man's zone.” This, combined with a high risk of complications, including tendon adhesions, precludes primary ED repair.
Zone I. The region includes the FDP tendon from the fingertip to the middle phalanx distal to the FDS tendon insertion.

Zone II. The FDP and FDS tendons extend between the middle phalanx and distal palmar crease. Proximal to zone II, the FDS tendons are superficial to the FDP tendon. The FDS tendon splits into two slips (Camper chiasm) across the proximal phalanx, allowing the FDP tendon to pass between them before the slips insert on the middle phalanx. A fibrocartilage matrix surrounds these tendons, creating a pulley mechanism that assists with isolated DIP and PIP flexion and prevents bowstringing.

Zone III. Known as the lumbrical zone, the region extends from the distal palmar crease to the distal edge of the flexor carpal ligament.

Zones IV and V. The carpal tunnel is included in zone IV. Zone V incorporates the proximal anterior forearm tendons and their distal musculature.

Clinical Features. Up to 90% of palmaris aponeurosis injuries are associated with tendinous and neurovascular injury, including injuries to arteries, median and ulnar nerves, FDS and FDP tendons, and lumbricals. Passive resting flexion should result in increasingly greater degrees of flexion from the index through the little finger (see Fig. 43.34). Complete disruption of the FDP tendon results in an extended resting position of the DIP joint. Reduced pinch and grip strength may also occur. FDS tendon injuries may result in a reduced resting flexion at the PIP joint.

FDP and FDS tendons’ strength and integrity should be tested separately. FDP tendon injury is suspected with subjective weakness or abnormal position of the hand at rest or pain and weakness with DIP joint flexion against resistance. Lacerations at the MCP joint crease may result in FDS tendon injury; as the FDS tendon bifurcates for the FDP tendon along the proximal phalanx, the FDP tendon paradoxically becomes the superficial tendon at the PIP joint crease (see Fig. 43.17). Therefore, wounds involving the PIP and DIP joint creases may involve the FDP tendon.

Finger FDP function is assessed by asking the patient to flex the DIP joints of each digit individually while the corresponding DIP joints are stabilized in extension by the examiner. Conversely, the FDS tendon of the individual finger is checked by asking the patient to flex the corresponding PIP joint while the adjacent digits are held in extension by the examiner (see Fig. 43.18). Because the FDP tendons share a common muscle belly in the forearm, extension of the adjacent digits will impede function of the tested finger’s FDP tendon, thus allowing the FDS tendon to be tested independently. Normal anatomic variations this include an independent FDP tendon muscle belly of the index finger and
Volar should be closed with 5-0 nonabsorbable sutures after decontamination, followed by immobilization of the hand, with the wrist in 10 to 15 degrees of flexion. Urgent follow-up evaluation with vascular and concurrent nerve injury. The neurovascular systems travel together within the palm and along the digits, and a careful neurologic evaluation should be performed to exclude concurrent nerve injury (see Figs. 43.23, 43.25, and 43.26).

Clinical findings may include pallor or cyanosis, delayed capillary refill, cool tissues, progressive pain or hyperesthesias, and reduced or absent pulses. The modified Allen test, pulse oximetry, or Doppler ultrasound may help assess regional vascular integrity. Ischemic pain is the most common initial complaint of patients with vascular insufficiency, often accompanied by pallor in the affected area.

Management

Meticulous physical examination is necessary to exclude occult vascular and concurrent nerve injury. Hand lacerations rarely cause life-threatening hemorrhage because the arteries usually retract and constrict. However, they may bleed briskly, especially in patients on antiplatelet or anticoagulation therapy. Injuries involving the palmar arches may be difficult to visualize in the ED and often require surgical exploration for hemorrhage control. Direct pressure, use of a blood pressure cuff inflated to 30 mm Hg above systolic pressure, or a tourniquet may help control bleeding. Clamps and hemostats should not be used to control bleeding because adjacent nerves and tendons may be crushed.

Arterial repair is not mandatory in isolated arterial injuries with a normal distal vascular examination. However, repair is indicated with tissue ischemia or associated nerve injury. If an artery is to be ligated, both ends should be closed, because these valveless vessels can back-bleed from collaterals. Radiographs and ultrasound may help identify the cause of palpable tender masses and differentiate among a retained foreign body, hematoma, infection, pseudoaneurysm, or arteriovenous fistula.

Nerve Injuries

Three classifications help define neural injuries resulting from blunt or penetrating trauma to the hand. The motor and sensory distributions distal to the injury should be carefully examined to identify nerve injuries (see Figs. 43.22 to 43.24). Neurapraxia is characterized by complete or partial dysfunction, commonly caused by prolonged compression or crush injury. The nerve’s axon, sheath, and endoneurium remain intact. Complete recovery commonly occurs within days to weeks. Axonotmesis results from disruption of the axon and myelin sheath, resulting in distal axonal degeneration. The endoneurial tube remains intact, allowing the proximal axonal stump to regenerate along the tube at a rate of 1 to 3 mm/day. Functional recovery is variable. Penetrating wounds commonly result in neurotmesis, in which all or a portion of the nerve elements are separated. Axonal regeneration does not occur unless the severed components are reapproximated.

Management

Patients with nerve injuries caused by blunt trauma should be splinted in the functional position and referred to a hand specialist to differentiate surgically amenable neurotmesis from conservatively treated axonotmesis. For penetrating trauma, hand service consultation should be obtained for injuries to the motor branches of the ulnar and median nerves, as well as digital sensory nerve injuries proximal to the DIP joint crease on the radial aspect of the index finger, the ulnar aspect of the little finger, and both sides of the thumb. Delayed primary repair may be needed in complex

Complications. Timely identification, management, and consultation can lead to favorable outcomes. Adhesions, triggering, and bowstringing are potential complications.

Vascular Injuries

Vascular injuries may result from penetrating trauma such as puncture wounds, lacerations, injection injuries, and amputations. Blunt trauma, such as a crush injury, can create arterial thrombosis or false aneurysm. The hand and its digits possess an excellent collateral supply, and isolated arterial injuries seldom result in ischemia. Pulsatile bleeding at the time of injury, even if bleeding has ceased at the time of evaluation, should raise concern for arterial injury. The neurovascular systems travel together within the palm and along the digits, and a careful neurologic evaluation should be performed to exclude concurrent nerve injury (see Figs. 43.23, 43.25, and 43.26).

Clinical findings may include pallor or cyanosis, delayed capillary refill, cool tissues, progressive pain or hyperesthesias, and reduced or absent pulses. The modified Allen test, pulse oximetry, or Doppler ultrasound may help assess regional vascular integrity. Ischemic pain is the most common initial complaint of patients with vascular insufficiency, often accompanied by pallor in the affected area.

Management

Meticulous physical examination is necessary to exclude occult vascular and concurrent nerve injury. Hand lacerations rarely cause life-threatening hemorrhage because the arteries usually retract and constrict. However, they may bleed briskly, especially in patients on antiplatelet or anticoagulation therapy. Injuries involving the palmar arches may be difficult to visualize in the ED and often require surgical exploration for hemorrhage control. Penetrating wounds commonly result in neurotmesis, in which all or a portion of the nerve elements are separated. Axonal regeneration does not occur unless the severed components are reapproximated.

Management

Patients with nerve injuries caused by blunt trauma should be splinted in the functional position and referred to a hand specialist to differentiate surgically amenable neurotmesis from conservatively treated axonotmesis. For penetrating trauma, hand service consultation should be obtained for injuries to the motor branches of the ulnar and median nerves, as well as digital sensory nerve injuries proximal to the DIP joint crease on the radial aspect of the index finger, the ulnar aspect of the little finger, and both sides of the thumb. Delayed primary repair may be needed in complex
injuries, allowing for adequate decontamination, debridement, and recession of inflammatory swelling prior to closure.

Complications
Peripheral nerve injury can result in permanent motor dysfunction, muscle atrophy, chronic paresthesias, neuromas, and sympathetic dystrophy.

Amputations
Principles
Complete or partial traumatic amputations constitute 0.1% to 1% of all hand injuries. With few exceptions, all completely amputated parts should be considered for replantation, and all partial amputations should be assessed for revascularization. Crushed, mangled, or multilevel digital amputations have poorer prognoses. Proximal amputations tolerate less ischemia time; distal injuries have a higher replantation success rate. Sharp, guillotine-like injuries fare better than avulsion or crush injuries.

Although successful replantation of digits after up to 40 hours of warm ischemia has been reported, cooling of the affected part extends the average tolerated ischemic time by approximately twofold; muscle and bone tolerate up to 12 and 24 hours of cold ischemia, respectively. Amputations involving the thumb, multiple digits, hand at the level of the wrist, and all amputations in children should always be evaluated for replantation (Box 43.4). Because thumb loss results in 40% loss of hand function, all thumb amputations should be considered for salvage, regardless of the level or mechanism of injury. Similarly, all amputations in children should be considered for replantation; microscopic inspection of vessels and nerves will guide the decision.

Management
General management goals include control of hemorrhage, salvage of neurologic and musculotendinous function, preservation of amputated tissues, wound care, and expeditious consultation. Gross contaminants can be removed by irrigation with normal saline. The amputated part should then be wrapped in normal saline-moistened gauze, sealed in a dry plastic bag, and placed on ice in an insulated container. The stump should be covered with saline-moistened sterile dressings and elevated to reduce edema and control bleeding. Patients should receive appropriate antibiotic and tetanus prophylaxis. Partial amputations with vascular compromise should be irrigated, dressed, and splinted. Cold packs may be placed around the dressings to prevent warm ischemia.

Complications
Amputation completion or revision may be indicated when vascularity is unsalvageable. Successful reimplantations may require additional operative revision or suffer from hypoesthesia, hyperesthesia, or chronic stiffness.

Fingertip Amputations

Principles. Any portion of the digit distal to the DIP joint is contained in the fingertip and is a common site of injury. Preservation of length and sensation are goals of care.

Classification. Amputations involving the distal phalanx and nail bed are divided into zones (Figs. 43.39 and 43.40; see Fig. 43.26). Zone I injuries preserve the bone and proximal two-thirds of the nail bed. In zone II injuries, two-thirds of the nail bed has been lost, with exposure of bone. In zone III injuries, the entire nail bed is absent, with significant bone exposure.

Management. Preservation of length, especially of the thumb, and maintenance of pulp to pulp pinch of the index finger are primary goals. Treatment includes early and thorough wound care, devitalized tissue débridement, and assessment of the need for surgical revision. Wounds smaller than 1.0 cm without bone exposure may be managed through secondary intention healing in children and adults. Wounds with up to 0.5 cm of bony exposure may be managed by secondary granulation after dissection of the exposed bone below the soft tissue with a ronguer. Larger wounds with more bony exposure will often need operative revision. We recommend antibiotic prophylaxis for bone exposure because these wounds are considered contaminated.

Hand specialist consultation should be considered early for zones II and III injuries, as well as thumb or index finger involvement. Management options include primary or delayed intervention, including wound closure, reimplantation, skin grafts, and a variety of flap revisions (see Fig. 43.40). Avulsion wounds may require a flap to cover bone adequately and add tissue bulk to the fingertip. Nail bed revision with preservation of a minimum 0.5 cm of nail bed distal to the lunula will allow nail adherence to the underlying matrix.

Complications. Nail deformity from matrix loss, despite repair, is common. Neurovascular damage may result in chronic fingertip hyper- or hypoesthesia, along with temperature intolerance. Close hand service follow-up is important to monitor recovery for maximal functional outcome and return to activity.

Ring Avulsion Injuries. A deceleration, such as a fall when a ringed finger catches on an object, can lead to results ranging from partial skin degloving to complete amputation. Hand service should be consulted to determine further management, including microvascular repair with replantation, complex flap transfer, graft, and primary amputation.

Mutilating Injuries. Lawnmower, carpentry saws, and wood chippers can create permanently disabling injuries. The most common injuries involve the dominant hand, including the index and middle fingers. Hand service should be consulted to identify opportunities to preserve limb length and function, especially in pediatric cases.

---

**BOX 43.4**

**Classic Indications for and Contraindications to Replantation**

**INDICATIONS**
- Multiple digits
- Thumb
- Wrist and forearm
- Sharp amputations with minimal to moderate avulsion proximal to the elbow
- Single digits amputated between PIP joint and DIP joint (distal to flexor digitorum superficialis [FDS] insertion)
- All pediatric amputations

**CONTRAINDICATIONS**
- Amputations in unstable patients secondary to other life-threatening injuries
- Multiple-level amputations
- Self-inflicted amputations
- Single-digit amputations proximal to FDS insertion
in a high percentage of amputations as compared to grease and other viscous compounds. The velocity of injection and site of tissue penetration determine dispersion risk. Distal sites (eg, fingertips) carry a worse prognosis than proximal sites.

**Clinical Features**

Initial symptoms may be minimal, with an entrance wound appearing innocuous or even absent. However, the involved digit or hand can develop pain, swelling, pallor, and motion tenderness within hours. Careful serial examinations should be performed to document the extent of injury and associated evolving neurovascular dysfunction. Radiographs may help identify the degree of dispersion by identifying subcutaneous emphysema and radiopaque material.

**Management**

Emergent hand service consultation should be obtained to determine needed interventions, including decompression and débridement. Successful nonoperative management in the case of sterile water or air injection has been reported. ED management includes broad-spectrum antibiotics, splinting, limb elevation, and tetanus prophylaxis. Parenteral analgesia is recommended over regional nerve blocks, which can add to tissue pressures and promote neurovascular compromise.

**Compartment Syndrome in the Hand**

**Principles**

Increased interstitial pressures within a closed compartment can lead to impaired microcirculatory perfusion and tissue injury. Common culprits include trauma (eg, displaced fractures, crush injuries) and injection-related injuries (eg, IV drug–abuse related injection, envenomations, iatrogenic extravasation of IV material, high-pressure injection injuries). Fascial planes separate the palm into 10 individual compartments (Fig. 43.41). The flexor surface of the digits are also compartmentalized by fascia and skin at flexor creases.

**Clinical Features**

Severe pain out of proportion to the injury may be the only initial abnormality. Hyperesthesia or hypoesthesia in the distribution of the nerve(s) passing through the affected compartment may be an early abnormal symptom. Soft tissue swelling may not be as impressive as the degree of pain. Pain and tenderness will be aggravated by active and passive stretching of the tissues associated with the affected compartment. With progression, patients may develop decreased motor function and progressive vascular compromise.

**Management**

Prompt diagnosis and definitive therapy increase the odds of a favorable outcome. The hand service should be emergently consulted for surgical decompression and débridement. Envenomations should be treated with antivenins, when available, but should not delay surgical consultation.

**Infections of the Hand**

**Paronychia**

**Principles.** A paronychia is an infection involving the lateral nail fold, commonly caused by local trauma. It may evolve from
local cellulitis to an abscess with lymphangitic extension. S. aureus (including methicillin-resistant Staphylococcus aureus [MRSA]) is the most common pathogen, followed by streptococci, Pseudomonas, gram-negative bacteria, and anaerobic flora; herpes simplex virus may mimic (i.e., Herpetic whitlow; Fig. 43.42) or co-infect a paronychia. Adults and children are prone to infections from oral flora, commonly from nail biting and digit sucking. Refractory cases may result from atypical mycobacterium or fungal infections. Inflammation originates along the cuticle alongside the fingernail, but may progress to involve the entire nail fold. The process may also extend to involve the proximal nail (i.e., eponychium).

**Management.** Patients with local cellulitis without an abscess should be given oral antibiotics and instructed to soak the finger multiple times per day and keep it elevated. Those with local fluctuance should be drained by lifting the cuticle off the nail to release and drain the pus. More extensive lesions may require digital block followed by extended incision, parallel to the nail and under the eponychium (Fig. 43.43). To allow improved drainage in severe cases, up to 25% of the nail adjacent to the abscess can be excised from the nail bed, followed by irrigation and packing. Wound cultures are usually not indicated and antibiotics are not necessary unless there is extending cellulitis, lymphangitis, immunocompromised status, or recurrent infection. Most cases resolve with local wound care over 5 to 10 days. Complications may include osteomyelitis. Chronic indolent processes involving the perionychium may require prolonged treatment and should be referred to a hand surgeon or dermatologist.

**Felon**

**Principles.** A felon is an infection resulting from penetrating trauma involving the digital fat pad (the pulp) containing septations that extend vertically from the distal phalanx to the volar skin, creating a series of individual compartments, each of which can become inoculated. Local warmth and redness may progress to a swollen, throbbing, and tender pulp space from increased local pressure. Infection may persist despite surgical decompression and drainage attempts if all affected compartments are not treated. S. aureus (consider methicillin-resistant and methicillin-sensitive strains) is the most common isolated pathogen, although the cause may also be polymicrobial.

**Management.** After administering a digital block, a felon can be drained by an incision parallel to the length of the phalanx,
Oral antibiotics such as cephalexin or dicloxacillin—or trimethoprim-sulfamethoxazole or clindamycin for suspected MRSA or penicillin allergy—should be given for at least 5 days.

**Complications.** Untreated felon can lead to skin necrosis, sinus tract formation, and chronic drainage. Dorsal spread can lead to phalangeal tuft necrosis and osteomyelitis. Deep incision may injure the flexor tendon sheath. Incision and drainage of structures crossing the DIP flexor crease increases the risk of infection spread, flexor tenosynovitis, septic arthritis, and proximal osteomyelitis. Incisions affecting the neurovascular bundle may result in vascular insufficiency, fingertip anesthesia, or neuroma. Longitudinal volar fat pad incisions can result in thick scarring and fingertip anesthesia.

![Fig. 43.41. Midpalmar spaces.](image)

A. Cadaver specimen revealing the midpalm and associated structures. Shown are the metacarpal bones of the thumb (1) and index (2), middle (3), ring (4), and little (5) fingers (green). The thenar and hypothenar eminence musculature is separated from the central palmar structures by midpalmar (oblique) and hypothenar fibrous septa (yellow dotted lines). The thenar adductor and interosseus muscle spaces lie between the metacarpal bones (red). The flexor pollicis longus (FPL) tendon and digital flexor tendons of the midpalm (blue) pass just anterior to the thenar and midpalmar spaces (red ovals). B–E, This patient presented with severe progressive painful swelling and hyperesthesias involving the first web space and index and middle fingers after a puncture wound to the second web space (red arrow). The patient suffered from a progressive deep space process involving the interosseus and thenar spaces, requiring operative débridement. (Courtesy Dr. D.A. Stearns, Department of Emergency Medicine, Massachusetts General Hospital, Harvard Medical School, Boston.)
Herpetic Whitlow

**Principles.** A self-limited manifestation of human herpes simplex type 1 or 2, herpetic whitlow is the most common viral infection of the hand, often involving the distal fat pad through direct contact of the digit with vesicles or open wounds. Common risks include patients with genital herpes infection and children with gingivostomatitis. Formerly health care workers were at particular risk, although this has been significantly reduced by the use of protective gloves and proper hand hygiene.

**Clinical Features.** Usually, a single digit is involved, with local erythema, swelling, and painful pruritus (see Fig. 43.42). Systemic symptoms are absent, although the affected area can become secondarily infected. Clear vesicular lesions evolve over the erythematous area, coalesce, and ulcerate over a 2-week period. This latter stage may appear similar to a felon or paronychia, prompting a consideration for incision and drainage. However, incision and drainage is contraindicated in herpetic whitlow because it can lead to viral dissemination and secondary infection.

**Diagnostic Testing.** A diagnosis can be made clinically based on the overall appearance in the context of local recurrence and potential sources of inoculation. Although viral culture of the vesicular fluid has been the criterion standard because it can differentiate among herpes simple virus types with high specificity, the 24- to 48-hour turnaround time may be less optimal for disposition planning. The Tzanck smear of vesicle scrapings to identify Giemsa-stained viral inclusion multinucleated giant cells is insensitive. We recommend the more cost-effective and sensitive polymerase chain reaction (PCR) assay.

**Management.** Although lesions resolve spontaneously over a 3- to 4-week period, symptoms recur in up to 20% of cases. Goals of therapy include providing symptomatic relief and preventing transmission, especially oral and ocular inoculation. Topical antiviral therapy has not been shown to be of treatment or prophylactic benefit. Although oral acyclovir has been advocated for immunocompromised patients, the benefits remain less clear in immunocompetent patients.

**Complications.** Misdiagnosis of a bacterial cause such as felon or paronychia may lead to improper treatment. A careful history, search for concurrent vesicular lesions, and avoidance of local incision and drainage should be carried out. Viral culture or PCR assay should be considered in equivocal diagnoses, especially in immunocompromised patients.

Tenosynovitis

**Principles.** Synovial space infections involve the flexor tendon sheaths and associated bursae (see Figs. 43.18 and 43.19). Double-walled sheaths contain a visceral layer adjacent to the tendon and a parietal layer, extending from the midpalmar crease to just proximal of the DIP joint. The thumb and fifth digit sheaths are continuous with the radial and ulnar palmar bursae. The radial bursa surrounds the flexor pollicis longus tendon; the ulnar bursa surrounds the flexor digitorum superficialis and flexor digitorum profundus tendons. These bursae communicate with each other in approximately 80% of the population, facilitating the spread of horseshoe infections. The sheaths and associated bursae of the second, third, and fourth digits end at the midpalmar crease and do not communicate with each other or the palm. S. aureus,

**Fig. 43.43.** Drainage of paronychia. A, The eponychial fold is elevated from the nail to facilitate local drainage. B, A lateral incision may be necessary to expose and drain an extended collection. The lateral aspect of the nail (blue dashed line) is removed if infection tracks below it. C, Two incisions are required (blue dashed lines) if the infection tracks across the proximal nail. This also facilitates proximal nail removal if the infection tracks below it. (Courtesy Dr. D.A. Stearns, Department of Emergency Medicine, Massachusetts General Hospital, Harvard Medical School, Boston.)
streptococci, gram-negative organisms, and enterococci have been isolated from infections caused by penetrating injuries that violate the bursa and sheath or by hematogenous spread (e.g., endocarditis). Infection can spread rapidly and proximally to involve the midpalmar, lumbrical (second, third, and fourth digits), thenar, and hypothenar compartments.

**Clinical Features.** Clinical manifestations of tenosynovitis were first described by Kanavel. These include the following: (1) palpable tenderness along the tendon sheath; (2) pain on passive extension of the digit; (3) symmetric digital swelling; and (4) digit fixed in a semiflexed position. Although all signs may not be present, the first two findings are the most useful and consistent clinical findings. Early recognition can prevent proximal spread of infection because progressive inflammation of the space can lead to microvasculature compromise and necrosis.

**Management.** Patients with flexor tenosynovitis require hospital admission, IV antibiotics, immobilization, elevation of the affected extremity, and hand service consultation for possible operative irrigation and drainage. Surgery should be considered in severe cases and for those who fail to improve after 24 hours of conservative treatment. The flexor sheath is rarely affected alone, and overlying cellulitic skin changes should raise concern for concurrent proximal bursa or midpalmar space involvement. Late presentations are common in immunocompromised patients (e.g., diabetes mellitus) and in those suffering from peripheral neuropathy. In patients with infection after penetrating trauma, antibiotics should include antistaphylococcal coverage (e.g., cephalexin or dicloxacillin; vancomycin, trimethoprim-sulfamethoxazole, or clindamycin for suspected MRSA or penicillin allergy). Gonococcal infections should be considered in sexually active persons with atraumatic presentations. In these cases, we recommend empirical treatment with ceftriaxone pending final test results, including samplings of mucosal sites.

**Deep Space Infections**

**Principles.** There are superficial and deep facial compartments in the hand that are potential spaces for the origin and spread of infection from penetrating wounds, communicating adjacent spaces, or hematogenous spread. The three superficial
spaces include the dorsal subcutaneous space, subaponeurotic space, and interdigital web space. Three anterior palmar spaces include the thenar, hypothenar, and midpalmar spaces (see Fig. 43.30). Common pathogens include *S. aureus*, streptococci, and coliforms.

**Clinical Features.** Concurrent subcutaneous involvement is the rule, not the exception, and the emergency clinician should consider a deep space process with a clinical context, such as penetrating trauma. Symptoms include pain out of proportion to the clinical findings and deep space tenderness with digital motion. When inflamed, the dorsal subaponeurotic space creates diffuse swelling and erythema on the hand dorsum but can be distinguished from simple cellulitis by noting concurrent tenderness on digital extension.

A palmar puncture wound, deep blister, or infected callus at the MCP joint can evolve into an interdigital web space infection termed a *collar button abscess*. Volar spread of infection is limited by the tight adherence of skin to the palmar aponeurosis. The infection extends dorsally to involve the dorsal subcutaneous tissues. The involved web space will appear swollen and tender, with its adjacent digits lying abducted. Tenosynovitis of the first and second digits can extend into the thenar space, causing painful swelling of the thenar eminence and first web space. The thumb will be held in an abducted and flexed position. Midpalmar space infections may originate from tenosynovitis of the third, fourth, and fifth digits and present with pain and tenderness in the proximal palmar region, especially with motion of the fingers.

**Management.** Deep fascial space infections require hospital admission, IV antibiotics, immobilization, elevation, and hand service consultation to determine the need for operative exploration and drainage. Patients should receive IV antistaphylococcal coverage, such as cephalaxin, nafcillin, and fluoroquinolones. Alternatives include vancomycin for suspected MRSA and a third- or fourth-generation cephalosporin (eg, ceftazidine, cefepime) for suspected pseudomonal infection. For suspected hematogenous-induced osteomyelitis, whose pathogens include *S. aureus*, Enterobacteriaceae, streptococci, and *H. influenzae*, treatment should include a combination of a penicillinase-resistant synthetic penicillin and a third-generation cephalosporin. Alternates therapy includes vancomycin (for suspected MRSA) or clindamycin, a third-generation cephalosporin, and linezolid. Ciprofloxacin and rifampin may also be an appropriate combination therapy for adult patients. *S. aureus* and *Salmonella* spp. should be considered in patients with sickle cell anemia.

### Septic Arthritis

**Principles.** Infections are commonly caused by direct inoculation from penetrating injuries, spread from adjacent soft tissue infections (eg, felon, paronychia, tenosynovitis); hematogenous spread is a less common cause. *S. aureus* (MRSA and methicillin-sensitive *S. aureus*) and streptococci are common pathogens, whereas *Haemophilus influenzae*, *Pseudomonas aeruginosa*, coliforms, corynebacteria, and anaerobes are less common. Gono-

coccal infection should be considered in sexually active patients presenting with atraumatic mono- or polyarticular arthritis.

**Clinical Features.** With progressive swelling, the joint assumes a semiflexed position to accommodate maximum volume. The overlying skin is commonly erythematous and warm. Unlike tenosynovitis, the joint itself, not the length of the overlying tendon sheath, is extremely tender and guarded, allowing minimal passive motion. The patient is often unwilling to mobilize the affected joint.

**Management.** Arthrocentesis should be performed on suspected joints using a 20-gauge or larger needle to aspirate viscous fluid. Relative contraindications to arthrocentesis include coagulopathy and overlying soft tissue infection. Admission, immobilization, elevation, and hand service consultation for joint irrigation and débridement or closed joint catheter irrigation should be considered. Patients should receive IV antistaphylococcal coverage, such as cephalaxin or dicloxacillin; vancomycin, trimethoprim-sulfamethoxazole, or clindamycin should be used for suspected MRSA or penicillin allergy and ceftriaxone for suspected gonococcal infection.

### Osteomyelitis

Open fractures and spread from adjacent soft tissue infections are common causes of hand osteomyelitis, with an incidence from 1% to 11%, far lower than in long bone injuries. Wounds with gross contamination, significant soft tissue injury, and severe skeletal trauma are at highest risk.

**Clinical Features.** Usually insidious, fever, localized soft tissue redness, swelling, warmth, and tenderness should raise suspicion, especially in immunocompromised patients. Children and infants may refuse to use the limb due to pain and tenderness (pseudoparalysis). Laboratory studies such as complete blood count, erythrocyte sedimentation rate, C-reactive protein, procalcitonin, and cultures may increase suspicion in the clinical context, but do not have the sensitivity or specificity of bone biopsy or aspirate cultures. Radiographic images may show overlying soft tissue edema as early as 3 to 5 days; periosteal elevation and early bone destruction may be seen at 14 to 28 days.

**Management.** Early hand specialist consultation is recommended for assistance with definitive management, which may include surgical débridement or hyperbaric oxygen therapy. Infectious disease consultation may be warranted, especially for immunocompromised patients.

Common pathogens resulting from trauma include *S. aureus*, *Bacteroides fragilis*, *P. aeruginosa*. Primary coverage may include cephalaxin, nafcillin, and fluoroquinolones. Alternatives include vancomycin for suspected MRSA and a third- or fourth-generation cephalosporin (eg, ceftazidine, cefepime) for suspected pseudomonal infection. For suspected hematogenous-induced osteomyelitis, whose pathogens include *S. aureus*, Enterobacteriaceae, streptococci, and *H. influenzae*, treatment should include a combination of a penicillinase-resistant synthetic penicillin and a third-generation cephalosporin. Alternate therapy includes vancomycin (for suspected MRSA) or clindamycin, a third-generation cephalosporin, and linezolid. Ciprofloxacin and rifampin may also be an appropriate combination therapy for adult patients. *S. aureus* and *Salmonella* spp. should be considered in patients with sickle cell anemia.

### Nontraumatic Disorders of the Hand

#### Stenosing Tenosynovitis

Stenosing tenosynovitis (ie, trigger finger or thumb, texting tendinitis, so-called Game Boy thumb) is caused by nodular thickening of the flexor tendon sheath, leading to a focal stenosis that prevents smooth passage of the associated tendon. As a result, the patient experiences painful and delayed extension of the digit. Causes can be traumatic, infectious, rheumatologic, inflammatory, or congenital. The MCP joint is the most frequent location, with the middle and ring fingers most commonly involved. Patients often describe a click or popping sensation after having to extend the digit forcefully; eventually, the digit remains locked in place, requiring manual extension of the digit. Patients should be referred to a hand specialist. Temporizing therapy may include local injection of steroids and 1% lidocaine placed into the tendon sheath at the stenosis; the digit is then immobilized in extension.

### Ganglion

A ganglion, the most common soft tissue tumor of the hand, is a synovial cyst consisting of degenerated collagenous connective
tissue that has herniated from a joint or tendon sheath. The condition grows insidiously, without a clear inciting event, and is common along flexor tendon sheaths and the wrist. Chief complaints include a dull ache and localized pain over the structure. Although large or tender ganglion cysts may be aspirated, they commonly recur and often require surgical arthroscopic or open excision for definitive removal. We recommend referral to a hand specialist.

**KEY CONCEPTS**

- Traumatic, infectious, and inflammatory conditions involving the hand are among the most commonly encountered problems in the ED.
- Obtaining a thorough history and performing a meticulous physical examination of the hand are paramount to the evaluation and development of an appropriate management strategy. Diagnostic imagery should be obtained with clinical suspicion.
- Timely and accurate evaluation and management yield the best functional outcomes with traumatic and infectious conditions of hand.
- Management of the acute hand condition should focus on maximizing function and minimizing long-term disability.
- Recognition of the need for hand specialist consultation or referral is extremely important for obtaining the best functional outcome for the patient.

CHAPTER 43: QUESTIONS & ANSWERS

43.1. A 25-year-old man presents with a painful laceration of the forearm following a bicycle accident. The laceration transects the supinator muscle. The patient’s physical examination shows his fingers held in flexion at the metacarpophalangeal (MCP) joint and thumb held in adduction. Which anatomic structure has been injured?
A. Median nerve
B. Musculocutaneous nerve
C. Radial artery
D. Radial nerve
E. Ulnar nerve

Answer: D. Motor function of the radial nerve is tested by having the patient extend the wrist against resistance. Proximal injury to the radial nerve causes a condition known as wristdrop, in which the fingers are held in flexion at the MCP joints, and the thumb is adducted.

43.2. A young man presents after a fight complaining of a cut on his finger. On physical examination, you note a deformity to the distal second phalanx, with a laceration to the second MCP joint. What is the best management for this patient?
A. Antibiotics, splint, and follow-up with hand surgery
B. Irrigation, topical antibiotic, and splint
C. Radiography, hand surgery consult, and antibiotics
D. Radiography, laceration repair, and splint
E. Radiography, urgent hand surgery follow-up, and cephalosporin

Answer: C. Lacerations or puncture wounds over the dorsum of the MCP joint associated with a metacarpal head fracture should be considered open until proved otherwise. Such injuries are often caused by a clenched fist injury and are highly contaminated wounds. Emergent consultation with a hand surgeon for operative débridement and irrigation is recommended. Prophylactic coverage with a cephalosporin is routinely recommended, although those with highly contaminated wounds also should receive penicillin with a β-lactamase inhibitor and an aminoglycoside.

43.3. A 27-year-old woman was playing basketball and jammed her ring finger on the basketball. She presents with her ring finger held in flexion at the proximal interphalangeal (PIP) joint and hyperextension at the distal interphalangeal (DIP) and MCP joints. What is the next step in the management of this patient?
A. Splint PIP in extension, allowing free movement of DIP and MCP.
B. Splint PIP in extension, MCP in flexion.
C. Splint PIP in extension, with full immobilization of digit.
D. Splint PIP in slight flexion allowing free movement of DIP and MCP.
E. Splint PIP in 90 degrees of flexion and extension of DIP and MCP.

Answer: A. This patient presents with a boutonnière deformity, which is a disruption of the central tendon, causing disruption in the extensor mechanism of the finger. Patients with suspected closed central tendon injuries should be treated with splinting of the PIP joint in full extension for 5 or 6 weeks. Only the PIP joint should be immobilized, and passive and active DIP joint flexion is encouraged from the outset. Operative repair may be required for an acute, closed boutonnière injury associated with a displaced avulsion fracture and injury with volar PIP joint dislocation. Early referral to a hand surgeon is advised.

43.4. A mechanic presents with a complaint of right index finger fusiform swelling and pain following an injection injury with a grease gun. Which of the following approaches best describes the appropriate management?
A. Digital block, elevation, and urgent surgical consult
B. Digital block, splint, and outpatient antibiotics
C. Digital block, splint, and urgent surgical consult
D. Parenteral pain medication, splint, and emergent surgical consult
E. Parenteral pain medication, splint, and outpatient surgical evaluation

Answer: D. Initial emergency department (ED) management includes splinting, elevation, tetanus prophylaxis, analgesia, and broad-spectrum antibiotics. Digital blocks are contraindicated because of the potential for increased tissue pressure, which may aggravate vascular compromise. Emergent hand surgery consultation is warranted because most cases require early extensive surgical decompression and débridement.
43.5. Which of the following are diagnostic criteria for flexor tenosynovitis?
A. Flexor contracture, flexor fluid fluctuation, digit held in flexion, flexor erythema
B. Flexor tendon tenderness, pain on passive flexion, symmetric swelling, digit held in flexion
C. Flexor tendon tenderness, symmetric swelling, pain on passive extension, digit held in flexion
D. Pain, paresthesias, pulselessness, pallor
E. Pain out of proportion to physical examination

Answer: C. Four cardinal signs of acute flexor tenosynovitis (Kanavel’s signs) are usually present and help differentiate tenosynovitis from other soft tissue infections in the hand: (1) tenderness along the course of the flexor tendon; (2) symmetric swelling of the finger; (3) pain on passive extension; and (4) a flexed posture of the finger. All four signs may not be present early in the course of infection.

43.6. How much angulation is acceptable in a metacarpal neck fracture?
A. 20 degrees at index finger
B. 25 degrees at middle finger
C. 35 degrees at index finger
D. 45 degrees at little finger
E. 50 degrees at index finger

Answer: D. Generally, less than 15 degrees angulation is allowed in the index and long finger metacarpals; in the ring and little finger metacarpals, 35 and 45 degrees of angulation are allowed, respectively. Any rotational misalignment should be completely corrected.

43.7. A 30-year-old woman presents after getting her index finger caught in her car door. Examination of the finger reveals a dark red discoloration beneath the nail involving approximately 25% of the nail. The nail is intact and the nail margins are not disrupted. Radiographs are negative. What is the most appropriate management?
A. Consult with hand surgery
B. Nail trephination
C. Oral pain medication, arrangements for follow-up
D. Performance of a digital block
E. Removal of the nail and repair of the nail bed laceration

Answer: C. Small subungual hematomas do not require drainage; the blood is incorporated into the nail and eventually removed with the free edge. Large (>50% of the nail) hematomas cause significant discomfort and should be removed by nail trephination.

43.8. A 42-year-old man presents with a painful swollen tip of his index finger. Four days earlier, he sustained a puncture wound to his fingertip. The physical examination is significant for tenderness, swelling, redness, and increased pressure in the distal pulp space of the affected finger. Which of the following is the best management strategy?
A. Deep midline volar incision to the flexor tendon sheath
B. Finger splint, oral antibiotics
C. Fishmouth incision
D. Intravenous antibiotics, emergent hand surgery consult
E. Lateral incision along the ulnar aspect of the fingertip

Answer: E. Felons are traditionally managed with incision through the septa to drain and relieve pressure in septal compartments. Most felons can be drained by a single lateral incision. The incision should be made along the ulnar aspect of the index, middle, and ring fingers and the radial aspects of the thumb and little finger, avoiding pincher surfaces. Fishmouth incisions may destroy the blood supply to the fingertip. Any incision that is made too deeply and proximally can injure the flexor tendon sheath, initiating a tenosynovitis.

43.9. Which of the following statements regarding foreign bodies in the hand is true?
A. A single radiograph is sufficient when looking for foreign bodies
B. Hand foreign bodies should always be removed emergently.
C. Magnetic resonance imaging (MRI) can improve the ability to detect foreign bodies.
D. Most glass foreign bodies are radiographically occult.
E. Wooden foreign bodies are readily visible on plain radiography.

Answer: C. Radiography is the best method for detecting radiopaque foreign bodies, including most glass. Radiographs should be taken using a soft tissue technique, with multiple views. Wooden foreign bodies are difficult to visualize radiographically. MRI, computed tomography (CT), and ultrasound can identify radiographically occult foreign bodies. Decisions regarding the necessity and timeliness of foreign body removal are based on the size and reactivity of the foreign body, proximity to vital structures, degree of wound contamination, and presence or absence of symptoms.

43.10. What is the proper ED management of a closed mallet finger injury?
A. Splint the DIP and PIP joints in extension.
B. Splint the DIP and PIP joints in extension and MCP joint in flexion.
C. Splint the DIP joint in flexion.
D. Splint the DIP joint in slight hyperextension.
E. Splint the DIP and PIP joints in flexion.

Answer: D. The management of a closed mallet finger injury consists of maintaining continuous DIP extension for 6 to 8 weeks, allowing for tendon healing to occur. The DIP joint is immobilized in slight hyperextension, but the PIP and MCP joints are allowed to move freely. An excessive degree of hyperextension should be avoided because this can lead to skin necrosis on the dorsal surface of the DIP joint.
WRIST

PRINCIPLES

The wrist joint is broadly defined as the anatomic area from the distal radius and ulna bones of the forearm to the carpometacarpal joints of the hand. It is anatomically and biomechanically complex, allowing for diverse functional capabilities. In the setting of trauma, this area is exposed, mobile, and at high risk of injury. Detailed knowledge of relevant anatomy, mechanism of injury, accurate clinical assessment, and radiograph interpretation are essential for proper emergent diagnosis and treatment.

ANATOMY AND PHYSIOLOGY

The wrist is composed of many complex articulations, including the radiocarpal, midcarpal, and distal radial ulnar joints (DRUJs), allowing for flexion, extension, abduction (radial deviation), adduction (ulnar deviation), and circumduction movements. Pronation and supination of the hand are primarily movements of the forearm occurring at the proximal radial ulnar joint and DRUJ.

The wrist includes the distal radius, ulna, and eight carpal bones, which are arranged in two transverse rows and are commonly referred to as the carpus (Fig. 44.1). Each carpal row contains four bones. The more mobile, proximal row, listed radial to ulnar, consists of the scaphoid, lunate, triquetrum, and pisiform bones and the distal row consists of the trapezium, trapezoid, capitate, and hamate bones.

The radius has three articular surfaces at the wrist—radiocarpal joint, DRUJ, and an interface with the triangular fibrocartilage complex (TFCC), also known as the articular disk. Only the distal radius articulates directly with the carpus via the scaphoid and lunate bones, which form the commonly referred to wrist joint. The ulna is separated from direct articulation with the proximal carpal row by the TFCC. This articular disk binds the distal ends of the radius, ulna, lunate, and triquetrum together. The DRUJ is a synovial pivot where the distal radius articulates and rotates around the relatively fixed ulna, and this joint is primarily stabilized by the TFCC.

Aside from the pisiform, which is considered to be a sesamoid bone embedded within the flexor carpi ulnaris (FCU) tendon, the carpus bones are lined by synovium that creates a continuous capsule throughout the intercarpal joints, distally to the metacarpal articulations. The only muscular insertions that occur throughout the carpus are the origin of the abductor digiti minimi from the pisiform and the point at which the FCU tendon inserts onto the hook of the hamate. As a result, nearly all carpal bone movements are passive, based on muscular insertions on the distal radius, ulna, and metacarpal bases.

The stabilizing ligaments of the wrist are divided into two major groups, the intrinsic and extrinsic ligaments. The intrinsic ligaments interconnect the individual carpal bones, and the extrinsic ligaments link the carpal bones to the distal radius, ulna, and metacarpals. The intrinsics are named for the adjacent bones to which they connect; the most important for maintaining carpal stability are the scapholunate and lunotriquetral ligaments. The extrinsics are divided into volar and dorsal groups. The volar extrinsic ligaments are divided into two V-shaped ligamentous bands called the proximal and distal arcades, which generally are thicker and stronger than the dorsal extrinsic ligaments and are the most important in providing stability to the wrist. Between these volar arcades is an area relatively devoid of ligamentous support, called the space of Poirier. This space enlarges when the wrist is dorsiflexed, and an injury to the joint capsule in this region can result in significant carpal instability (Fig. 44.2).

Most structures that cross the wrist joint are contained within individual compartments formed by the deep fascia of the wrist. On the dorsal surface of the wrist, the extensor tendons are divided by the extensor retinaculum into six compartments, each having a separate synovial sheath that extends proximally and distally to the retinaculum. On the volar surface of the wrist, the flexors of the digits and median nerve are contained within the carpal tunnel, which is formed by the flexor retinaculum superficially and its attachments to the carpal bones. Radially, the flexor retinaculum attaches to the scaphoid tubercle and ridge of the trapezium. On the ulnar side, it attaches to the pisiform and hook of the hamate. Both the trapezoid and capitate bones form the floor of the carpal tunnel. Radially and superficially to the carpal tunnel, the flexor carpi radialis tendon crosses the wrist joint in its own compartment.

The vascular supply to the wrist is provided by the radial and ulnar arteries, which join in a series of dorsal and palmar arches to supply the bones of the carpus. The intrinsic blood supply to most carpal bones enters the distal portion, leaving the proximal area at risk for devascularization and avascular necrosis (AVN) when fractured. This is particularly true for the scaphoid, capitate, and lunate bones, which receive their blood supply commonly from a single distal vessel (Fig. 44.3).

The wrist and hand are innervated by the radial, median, and ulnar nerves. The radial nerve and dorsal sensory branch of the ulnar nerve cross the dorsum of the wrist near the radial and ulnar styloids, respectively. The median nerve crosses within the carpal tunnel on the volar aspect of the wrist, just radial and deep to the palmaris longus tendon. The ulnar nerve is within Guyon’s canal, between the pisiform and hook of the hamate (see Fig. 44.3). In the setting of trauma, motor and sensory function of the radial, median, and ulnar nerves may be assessed at the wrist and distally, based on common clinical examinations (Table 44.1).

CLINICAL FEATURES

The clinical examination of the patient with a wrist injury begins with a complete history, including the mechanism of injury and site of maximal pain or tenderness. Most wrist injuries are caused by a fall on the outstretched hand. The physical examination begins with inspection of the wrist, with the opposite uninjured wrist used as the normal reference; it includes an assessment of
the presence of swelling, discoloration, or obvious deformity and ability of the patient to move the joint through a normal range of motion.

Several bony prominences serve as useful landmarks; their locations are best described in relation to the two major lateral and medial reference points in the wrist, the radial and ulnar styloids, respectively. Just distal to the radial styloid is the anatomic snuffbox, bordered radially by the abductor pollicis longus (APL) and extensor pollicis brevis (EPB) tendons and ulnarly by the extensor pollicis longus (EPL) tendon. The body of the scaphoid is palpable within the snuffbox and is more prominent with the wrist in ulnar deviation. Lister’s tubercle can be palpated just distal to the wrist crease. In addition, a rounded prominence at the base of the thenar muscles and is especially prominent when the wrist is extended. On the ulnar border of the wrist, the pisiform is palpable at the base of the hypothenar muscles, just distal to the wrist crease. In addition, approximately 1 cm distal and radial to this point, the prominence formed by the hook of the hamate can be palpated.

The clinical examination also includes an assessment of neurovascular status. Radial and ulnar pulses are easily palpable on the volar surface of the wrist, and the presence of adequate circulation should be assessed in injuries to the wrist.

**DIAGNOSTIC TESTING: RADIOLOGY**

Plain radiographs remain the cornerstone of emergent diagnosis of trauma to the wrist. Routine radiographic views include the posteroanterior (PA), lateral, and oblique projections, each obtained with the wrist in neutral position. Accurate interpretation of these views requires knowledge of the normal appearance and anatomic relationships of the distal radius, ulna, and carpal bones.

On a correctly positioned PA view of the wrist, the ulnar styloid rises from the lateral aspect of the distal ulna; the extensor
carpi ulnaris (ECU) tendon groove should be visualized at, or radial to, its base. The radial styloid process extends beyond the end of the articular surface of the ulna by a normal distance of 9 to 12 mm. This normal difference in length is called the radial length measurement (Fig. 44.4). There may be some degree of ulnar variance that affects the radial length measurement on a PA radiograph. The distal articular surface of the ulna may terminate before, at, or distal to the radiolunate articulation as a result of wrist rotation, flexion, extension, anatomic variation, or injury. Neutral ulnar variance (as seen in Fig. 44.4) is described when the distal ulnar and radiolunate articular surfaces terminate at the same point. A positive ulnar variance (ulnar articulation is more distal) or negative ulnar variance (ulnar articulation is more proximal) is independent of styloid size and may be associated

Fig. 44.2. Ligaments of the wrist. A, The volar extrinsic ligaments are most important in providing stability to the wrist. These include the radial collateral, radiocapitate, radioscapohoid, radiotriquetral, ulnotriquetral, capitotriquetral, and ulnar collateral ligaments. The space of Poirier (*) is a gap in the volar ligaments and the site of potential weakness. B, The intrinsic (intercarpal) ligaments connect the individual carpal bones. The most important of these are the scapholunate and lunotriquetral ligaments. (Adapted from Netter FH: Atlas of human anatomy, ed 3, Teterboro, NJ, 2003, Icon.)
The normal volar tilt of the distal radial articular surface is visible on the lateral view of the wrist and typically measures 10 to 25 degrees (Fig. 44.6). Adequacy of a lateral view of the wrist is assessed based on the relationship among the scaphoid, pisiform, and capitate projections. The palmar cortex of the pisiform with wrist pathology (eg, ulnar impaction syndrome and Kienbock’s disease, respectively). The ulnar slant of the articular surface of the radius, referred to as radial inclination, is visible on the PA view and normally measures 15 to 25 degrees (see Fig. 44.4). Both these measurements are important in assessing the degree of radial shortening seen in association with some fractures of the distal radius. The normal appearance of the carpus on the PA view shows an approximately equal distance (usually 1 to 2 mm) between each of the carpal bones, and opposing articular surfaces are parallel to one another (an arrangement known as parallelism). On radiographs, three smooth curves normally can be drawn along the articular articular surfaces, known as carpal or Gilula’s arcs (Fig. 44.5). Disruption of these curves or widening of the carpal spaces is an indication of carpal ligament disruption, instability, or fracture.¹

Fig. 44.3. Vascular supply to the wrist. Note the relationship of the ligaments to the neurovascular supply to the wrist. (Adapted from Netter FH: Atlas of human anatomy, ed 3, Teterboro, NJ, 2003, Icon.)

Fig. 44.4. Normal radiographic appearance of the wrist on a posteroanterior view. The ulnar styloid arises from the lateral aspect of the distal ulna, and the tendon groove for the extensor carpi ulnaris should be visualized at, or radial to, its base. A, Radial length measurement with neutral ulnar variance. The radial styloid extends 9 to 12 mm beyond the articular surface of the distal ulna. The ulna may terminate distal, at, or proximal to, the radiolunate articulation affecting radial length measurement with a positive, neutral, or negative variance, respectively. B, The ulnar slant of the distal radius (angle ab) normally measures 15 to 25 degrees. (From Greenspan A: Orthopedic radiology: a practical approach, ed 2, New York, 1992, Gower Medical.)

Fig. 44.5. Carpal (Gilula’s) arcs. On a posteroanterior radiograph of the wrist, three arcuate lines (1 to 3) can be drawn along the articular surfaces. Although small indentations at joint lines may occur, a step-off or broken arc suggests fracture, ligamentous instability, or disruption of the wrist.

The normal volar tilt of the distal radial articular surface is visible on the lateral view of the wrist and typically measures 10 to 25 degrees (Fig. 44.6). Adequacy of a lateral view of the wrist is assessed based on the relationship among the scaphoid, pisiform, and capitate projections. The palmar cortex of the pisiform
should project midway between the palmar margins of the distal pole of the scaphoid and capitare head, forming the S-P-C lateral (Fig. 44.7). The normal alignment of the distal radius with the lunate and capitare also is seen on the lateral view, which will show two concentric cups—the cup of the distal radius containing the lunate and the cup of the distal lunate containing the capitare. Ideally, the long axis of the radius, lunate, capitare, and third metacarpal should appear as a straight line on the lateral view, although the so-called normal alignment usually is within 10 degrees of this line (Fig. 44.8). The carpal alignment on the lateral view is defined further by the scapholunate angle, which should measure 30 to 60 degrees, and capitolarunate angle, which is 0 to 30 degrees (Fig. 44.9). Abnormalities in these angles are seen in patients with carpal ligament injuries and instability.

The soft tissues of the wrist also offer valuable clues to the presence of underlying bony injuries. It is estimated that on 90% of normal lateral radiographs of the wrist, the pronator quadratus line is visible as a linear, lucent, fat collection in the volar soft tissues just anterior to the distal radius (Fig. 44.10). Fractures of the distal radius or ulna result in a pronator quadratus sign representing volar displacement, anterior bowing, or complete obliteration of this line. Although this sign may suggest injury, a wide range of sensitivities has been quoted, so, its absence does not exclude a fracture. A positive pronator quadratus sign has also been observed in soft tissue injuries, as well as infectious and inflammatory medical conditions.

Many wrist injuries are occult and may not be identified or clearly characterized by routine wrist radiographs. Additional radiographic imaging of the wrist may assist the emergency clinician with diagnosis based on chief complaint, mechanism of injury, or physical examination findings, including specific areas of tenderness. In addition to the standard PA, lateral, and oblique wrist radiographs, adjunct imaging may include views with ulnar and radial deviation, maximal flexion, extension, carpal tunnel view, reverse (supinated) oblique, clenched fist PA, or anteroposterior (AP) views. Emergent patient-specific imaging helps delineate otherwise occult fractures or abnormal motion of the carpus resulting from ligamentous injuries further. When a scaphoid fracture is suspected, a pronated ulnar deviated view of the wrist, allows for better visualization of the bone along its long axis. The carpal tunnel view is performed with the wrist hyperextended and provides an axial volar image of bony margins. The carpal tunnel view and reverse (supinated) oblique help identify fractures involving the hook of the hamate and pisiform in the common clinical setting of hypothenar wrist trauma. The clenched fist, both PA and AP views, drive the capitare, proximally, as a wedge, causing diastasis within the scapholunate joint and highlighting ligamentous instability when tenderness is present (Table 44.2). Although scapholunate width may be exaggerated on the AP, instability is suspected when either view shows a distance of 3 mm or greater. Wrist views taken in maximal flexion or extension are typically used in more chronic ligamentous issues, such as volar and dorsal intercalated segmental instability.

Given the high incidence of occult injuries of the wrist, when radiographs are negative and significant pain persists, immobilization and a repeat examination, often accompanied by imaging, should be arranged after a period of 1 to 2 weeks. A thumb spica is usually added in the setting of suspected scaphoid fractures. Additionally, occult, fractures or soft tissue injuries may be diagnosed emergently, urgently, or on a routine basis with advanced computed tomography (CT) or magnetic resonance imaging (MRI) imaging protocols. Emergent CT or MRI wrist imaging is rarely, if ever, indicated in the emergency department (ED). Although advanced imaging occasionally identifies an otherwise occult injury, management and outcomes generally are not affected by this new diagnosis. The best data exist for scaphoid fractures (discussed below), for which CT and MRI protocols are

**Fig. 44.6.** Normal radiographic appearance of the wrist on a lateral view. The distal radius has a normal volar tilt (angle ab) of 10 to 25 degrees. (From Greenspan A: Orthopedic radiology: a practical approach, ed 2, New York, 1992, Gower Medical.)

**Fig. 44.7.** Normal S-P-C (scaphoid-pisiform-capitate) lateral view of the wrist. The palmar cortex of the pisiform (P) is shown bisecting the line between the palmar aspect of the scaphoid (S) and capitare (C) bones.

**Fig. 44.8.** Normal relationship of carpal bones on a lateral radiographic view. The concavity of the radius and lunate and convexity of capitare form three C-shaped areas (stippled) along a straight line that runs through the central axis of these bones.
Carpal Injuries

Scaphoid Fractures

The scaphoid is the most commonly fractured bone of the carpus.\textsuperscript{10,11} It accounts for approximately 70% of all carpal fractures and is typically seen in individuals 15 to 40 years of age.\textsuperscript{11} Scaphoid fractures most commonly occur after a fall on the outstretched hand, causing hyperextension of the wrist.\textsuperscript{11} These injuries are rare in skeletally immature patients because the carpus is composed entirely of cartilage at birth and remains predominantly cartilaginous until the adolescent years. In pediatric patients, although the physis of the radius is likely to fail first, scaphoid fractures, with and without a radial fracture have been observed. In older adults, a distal radius metaphysis fracture is more likely to occur. Scaphoid fractures are classified by their anatomic location and may be divided into three groups—fractures of the tuberosity and distal pole, waist, and proximal pole. Of these three patterns, fractures through the waist of the scaphoid are the most common, accounting for approximately 70% to 80% (Fig. 44.11).\textsuperscript{11,12}

approaching 100% sensitivity for injury. However, until more prospective and definitive research identifies clear value for emergent advanced imaging, we recommend immobilization, with follow-up in 1 to 2 weeks for reexamination and possible imaging at that time.
PART II
Common splint. Scaphoid arm, Short

Fig. 44.11. Scaphoid wrist fracture. A posteroanterior view of the wrist in ulnar deviation (scaphoid view) illustrates a nondisplaced fracture of the scaphoid waist (arrow).

Patients typically report radial-sided wrist pain distal to the styloid with decreased range of motion of the wrist and thumb. Classically, the physical examination reveals tenderness on palpation of the scaphoid within the anatomic snuffbox. For scaphoid tenderness to be elicited, a combination of maneuvers, such as ulnar deviation, palpation of the scaphoid tubercle volarly, a Watson’s scaphoid shift test, axial compression of the first metacarpal, resisted supination of the wrist and thumb, and subjective dorsal and volar radial pain illustrated by a thumb-index finger pinch on both sides of the wrist may have to be performed. The first meta-analysis of the diagnostic accuracy of physical examination findings in ED adult patients with occult scaphoid fractures was published in 2014. The conclusions of this study emphasized that except for the absence of snuffbox tenderness, which has a negative likelihood ratio of 0.15 for occult scaphoid fracture, physical examination findings lack accuracy to rule scaphoid fractures in or out, and no validated clinical decision rule exists. Therefore, in an attempt to avoid complications associated with delayed diagnosis, occult fracture displacement, and AVN, any patient with suspected scaphoid fracture should receive splint immobilization and repeat imaging within 1 to 2 weeks.

Radiographic diagnosis of scaphoid fractures is often difficult. An additional ulnar-deviated PA view of the wrist may assist with fracture visualization. A visible bone lucency or cortical disruption may be absent, and a more subtle change, such as bowing, obliteration, or displacement of the scaphoid fat pad may be the only clue that a wrist injury is present. However, these signs are not even reliably present, and plain radiographs taken soon after injury fail to detect fracture in approximately 15% of scaphoid injuries. Approximately one in four patients who presents with scaphoid tenderness, has initially negative x-rays, and is splinted, will subsequently be diagnosed with a scaphoid fracture. Recent evidence has called into question the practice of immobilizing the wrist in all patients with suspected scaphoid injuries and has suggested that the use of more advanced imaging modalities is accurate and cost-effective and should be performed earlier rather than later. The cost of time off from work, serial casting, repeat physician evaluation, and office visits easily exceed that of MRI, CT, or bone scans for definitive diagnosis where these imaging modalities are readily available. In addition to advanced imaging, clinical risk assessments and decision rules are being developed to help risk-stratify patients further.

Radiographic imaging remains the cornerstone for the evaluation of acute wrist trauma and, historically, bone scans were used 72 to 96 hours after injury to detect occult scaphoid fractures. Although high sensitivities are quoted (97%), lower specificities, many false-positives, decreased effectiveness in older adults, and limited availability have tempered their use. Macroradiography and ultrasound, including high-resolution sonography, have not approached the sensitivities and specificities observed with bone scintigraphy, CT, and MRI. CT and MRI imaging allow emergency clinicians to diagnose most radiographically occult scaphoid fractures. However, CT has not had the sensitivity required (93%) for diagnosing occult scaphoid fractures, nor alternative injuries, in the emergent setting, or that may still warrant wrist immobilization. As a result, CT may be used urgently for detailed bone imaging and operative planning, and it reveals the complications of fracture fragment displacement, malunion, and nonunion. Despite increased costs and more limited availability, MRI protocols have the advantage of allowing the diagnosis of alternative occult fractures or soft tissue injuries and are being used to detect scaphoid fractures, with purported sensitivity rates approaching 100%. Research reflecting emergent diagnostic management of wrist trauma with advanced MRI imaging may suffer from clearly defined diagnostic criterion standards, incorporation, and temporal bias inflating sensitivities of clinically significant disease. Despite extensive study and multiple adjunct imaging modality options, emergent advanced protocols remain investigational, calling for more prospective data.

The definitive treatment for uncomplicated, nondisplaced scaphoid fractures is debated among orthopedic specialists, although trends toward screw fixation over cast immobilization are evident. Emergency management typically involves immobilization in a thumb spica splint at 10 degrees of flexion with radial deviation, theoretically, used to stabilize fracture fragments of the scaphoid (Fig. 44.12). Most surgeons terminate the thumb spica at the interphalangeal joint line. Some specialists use a long arm (above the elbow) cast or splint, which prevents wrist pronation and supination for the first few weeks, while others prefer short arm immobilization. In addition to flexion and extension, pronation and supination have been suggested to produce fracture displacement in the proximal carpal row. The duration.
of immobilization varies relative to the location of the fracture, but 6 to 12 weeks is common. More proximal fractures commonly require longer durations to ensure adequate healing. Variability in healing time is related directly to the pattern of blood supply to the scaphoid, which flows from the distal to proximal portion of the bone through the scaphoid tuberosity. This pattern of blood flow also accounts for the higher incidence of AVN and nonunion seen in more proximal fractures (Fig. 44.13). As a result of these complications, true scaphoid fractures require urgent orthopedic referral for consideration of operative treatment.

Lunate Fractures
Fractures of the lunate are relatively uncommon and represent fewer than 5% of all carpal fractures. This injury occurs more commonly in persons with a congenitally short ulna, perhaps as a result of a compromised support for the TFCC. The usual mechanism of injury involves a fall on the outstretched hand, causing extreme dorsiflexion, with transmittal of the resultant force from the capitate to lunate. Patients have pain over the dorsum of the wrist, exacerbated by axial loading of the long finger metacarpal. On physical examination, tenderness may be elicited by palpation over the dorsum of the wrist in the depression felt just distal to Lister’s tubercle.

Fractures of the lunate may be difficult to see on plain radiographs because of overlap of the distal radius, ulna, and other carpal bones. For this reason, and because of the risk of AVN in missed injuries, clinically suspected lunate fractures should be immobilized. Nondisplaced lunate fractures are treated with immobilization, and displaced injuries require open reduction and internal fixation (ORIF). Lunate and perilunate dislocations are discussed later, in the section on carpal instability. Complications of lunate fractures include progression to carpal instability, nonunion, and AVN. Kienbock’s disease, defined by AVN of the lunate, has a predictable pattern of bony collapse, carpal change, and degeneration. Although poorly understood, it apparently results from a combination of vascular, anatomic, and traumatic mechanisms. In well-established cases of Kienbock’s disease, the lunate appears sclerotic and fragmented on radiographic examination, and ultimately the bone collapses, with resultant proximal migration of the capitate (Fig. 44.14). These changes cause secondary osteoarthritis of the radiocarpal joint, chronic wrist pain, and weakness. Treatment involves nonoperative and operative intervention, with correction of the articular abnormalities by lengthening the ulna or shortening the radius. In more advanced cases, excision and prosthetic replacement of the lunate or arthrodesis may be necessary.

Triquetal Fractures
Triquetral injuries, second only to the scaphoid in incidence, account for approximately 15% of carpal fractures. There are three main patterns observed, triquetal body and avulsion fractures volarly and as a dorsal cortical chip. Triquetral body and volar avulsion fractures are commonly associated with perilunate and lunate dislocations and, therefore, ligamentous injury should be considered. A fracture to the triquetral body is best seen on the AP radiograph, and urgent orthopedic referral is suggested. Dorsal triquetral chips appear to be an avulsion-type fracture with a more benign clinical course. The impact of a prominent ulnar styloid or proximal hamate bone against the triquetrum has been theorized as a possible mechanism of injury. On physical examination, patients will have local tenderness, and swelling may be noted in this area. Although the fracture is best seen on the standard lateral view of the wrist as a small dorsal avulsion fragment, a more oblique pronated view may be necessary for
Hamate Fractures

Hamate fractures are rare and account for approximately 5% of all carpal bone fractures.10,27 The hook or hamulus is the most common site of fracture, although articular surfaces and body fractures are also seen. Fracture of the hook usually occurs from a fall on the outstretched hand or from a direct blow to the palm. Typically, hook of the hamate fractures occur from those participating in racket or club sports (eg, tennis, golf, baseball). The use of hammers and vibration equipment (eg, jack hammers) is also a common mechanism, which can predispose workers to hamate fractures and ulnar canal and hypothenar hammer syndrome.28 Patients may have isolated pain over the hypothenar eminence, associated decreased grip strength, or compromised distal perfusion. Pain may be localized directly on palpation of the hamate, 1 cm distal and radial to the pisiform. Hamate body and articular surface fractures are usually caused by increased load to the ring and little finger metacarpals. These fracture patterns are best seen on PA views of the wrist (Fig. 44.17). Standard wrist radiographs have poor sensitivity for hamate hook fractures, which are more easily seen on reverse, supinated oblique, and carpal tunnel views (Fig. 44.18).

Nondisplaced fractures of the pisiform generally carry a good prognosis and are treated conservatively, with immobilization and orthopedic referral. Definitive treatment is with a short arm cast for 3 to 4 weeks. Most pisiform fractures with evidence of ulnar neurapraxia will resolve, but urgent orthopedic referral for consideration of surgical decompression is indicated. Pisiform fractures complicated by displacement, nonunion, and pain may also require excision.27

Fig. 44.15. Triquetral avulsion fracture. A minimally displaced triquetral avulsion or dorsal chip fracture (arrow) is seen on this lateral radiograph of the wrist.

Fig. 44.16. Pisiform fracture. A reverse supinated oblique radiograph of the wrist profiling the pisotriquetral joint demonstrates minimally displaced pisiform fracture (arrow) not typically seen on traditional posteroanterior, lateral, and oblique views.
CHAPTER 44  Wrist and Forearm

Wrist and Forearm also commonly occult. These injuries are treated with immobilization in a thumb spica splint, and patients are given orthopedic referral. Nondisplaced fractures are immobilized in a circumferential cast for 6 weeks, whereas displacement or involvement of the carpometacarpal joint warrants urgent orthopedic referral for ORIF.

Capitate Fractures

The capitate lies in a central position in the distal carpal row and, because of this protected location, it is rarely fractured. When fracture does occur, the mechanism generally is a direct blow to the dorsum of the wrist. Fracture also may be seen in association with a perilunate dislocation after a fall on the outstretched dorsiflexed hand. Clinical examination reveals dorsal wrist pain and swelling, with localized tenderness on palpation of the capitate. Fractures usually are visible on the standard PA view of the wrist, although the lateral view may be helpful in determining the presence of rotation or displacement of the fracture fragment.

Trapezium Fractures

Fractures of the trapezium are also uncommon and represent approximately 4% of all carpal fractures. There are two main types of fractures, those involving the body and trapezial ridge. A direct blow to the adducted thumb causes fracture through the body of the trapezium, with transmittal of the force by the base of the thumb metacarpal. Avulsion fractures of the trapezial ridge occur with forceful radial deviation or rotation of the wrist. On examination, patients report pain with movement of the thumb and on direct palpation of the trapezium, just distal to the scaphoid in the anatomic snuffbox. Although trapezium fractures may be seen on the AP view of the wrist, they are typically better visualized on oblique views (Fig. 44.19) and, unfortunately, are

Trapezoid Fractures

Trapezoid fractures are rare, usually seen in association with other carpal injuries, and account for only approximately 1% of all carpal fractures. The typical mechanism of injury is a direct blow down the long axis of the index metacarpal, which may result in
isolated fracture to the trapezoid or cause a dorsal fracture-dislocation. On clinical examination, pain and tenderness are localized over the dorsum of the wrist at the base of the second metacarpal. The fracture may be visible on routine PA views of the wrist; however, oblique views may be superior for visualization of the injury. Nondisplaced trapezoid fractures should be immobilized with a short arm splint and thumb spica, and patients are given an orthopedic referral. However, displaced fractures warrant urgent orthopedic referral for reduction and fixation.

Carpal Instability

Carpal ligamentous injury is caused by wrist hyperextension, ulnar deviation, and intercarpal supination. The Mayfield classification of carpal instability is comprised of four distinct stages. Each stage represents a sequential intercarpal injury, beginning with scapholunate joint disruption and proceeding around the lunate, creating progressive carpal instability (Fig. 44.20). Each stage may also be associated with specific bony fractures, which, if present, should alert the emergency clinician to the possibility of an occult perilunate ligamentous injury. These associated injury patterns include fractures of the radial styloid, scaphoid, capitate, and triquetrum.

A stage I injury, or scapholunate dissociation, results in a characteristic widening of the scapholunate joint on the PA view, which has been called the Terry Thomas sign after the British comedian with a gap between his front teeth. This radiographic sign has been updated to reference more current celebrity figures and is also referred to as the Madonna sign or David Letterman sign. This injury pattern may be associated with a rotary subluxation of the scaphoid. Radiographically, the scaphoid is seen end-on, with the cortex of the distal pole appearing as a ring shadow, referred to as the signet ring sign (Fig. 44.21). Scapholunate dissociation may not be demonstrated on routine radiographs, so when the clinical examination reveals tenderness to palpation, suggesting ligamentous injury, additional stress views could be considered. Radiographs taken with a clenched fist and with ulnar deviation (the clenched fist AP view) accentuate widening of the scapholunate joint and are suggestive of disease when a gap larger than 2 mm is observed.

A stage II injury, or perilunate dislocation, is seen best on the lateral view of the wrist. Although the lunate remains articulated to the distal radius, the capitate is dorsally dislocated. The PA view shows overlap of the distal and proximal carpal rows and also may show an associated scaphoid, radial styloid, or capitate fracture (Fig. 44.22).

A stage III injury appears identical to a stage II injury but includes a dislocation of the triquetrum that is seen best on the PA view, with overlap of the triquetrum on the lunate or hamate. This injury may be associated with a volar triquetral fracture.

A stage IV injury, or lunate dislocation, results in a characteristic triangular appearance of the lunate on the PA view caused by the rotation of the lunate in a volar direction. This triangular appearance is known as the piece of pie sign. This rotation also is visible on the lateral view of the wrist, in which the lunate looks like a cup tipped forward and spilling its contents, referred to as the spilled teacup sign. On the lateral view, the capitate is seen to lie posterior to the lunate and often has migrated proximally to contact the distal radius (Fig. 44.23). Mayfield dislocations are associated with radial styloid, scaphoid, capitate, and volar triquetral avulsions and dislocations. This injury pattern, with or without spontaneous lunate reduction, should alert the emergency clinician to ligamentous damage.

Patients with these carpal dislocation injuries typically have a history of a fall on the outstretched hand. They complain of pain and swelling over the dorsum of the wrist, with limited range of motion. On physical examination, tenderness to palpation is noted over the dorsum of the wrist, particularly in the region of the scapholunate ligament. Delayed scapholunate instability may be clinically elicited by a provocative maneuver, such as Watson’s scaphoid shift test, which will increase pain and produce a clunk or snap. The test is performed by placing upward pressure on the scaphoid tuberosity while the hand is in ulnar deviation. In scapholunate instability, this action will cause the scaphoid to ride out of the radial fossa over the dorsal rim and, as the hand is moved back radially, a painful snap is produced. In the setting of acute trauma, unfortunately, this test is too painful to perform.
Fig. 44.22. Perilunate dislocation. A, This posteroanterior view of the wrist shows an abnormal-appearing lunate bone, obvious disruption of the normal carpal arcs, and commonly associated and, in this case, displaced scaphoid fracture. B, Lateral view shows a dislocated and dorsally displaced capitate bone in relation to the lunate. Of note, the lunate maintains its articular connection and alignment with the radius, suggesting perilunate dislocation.

Fig. 44.23. Lunate dislocation. A, This posteroanterior view shows the characteristic triangular shape of the lunate bone during dislocation. B, Volar displacement of the lunate resembles a spilled teacup on the lateral view. Note the disrupted articulation between the lunate and distal radius and realignment of the radius, capitate, and metacarpals, suggesting lunate dislocation.
MRI has relatively low sensitivity and specificity for the diagnosis of scapholunate injury; arthroscopy remains the gold standard for diagnosis. Arthroscopy is considered to have superior detection ability for the internal derangement of wrist ligaments and a more accurate visualization of the articular surfaces. With perilunate and lunate dislocations, visible deformity of the wrist also is apparent, and two-point sensation in the median nerve distribution often is diminished. Carpal dislocation injuries need emergent orthopedic consultation in the ED for reduction and stabilization. Complications of carpal dislocation injuries include median nerve injury and chronic carpal instability, with resultant degenerative arthritis.

**Radiocarpal Instability and Dislocation**

Although radiocarpal dislocations and fracture-dislocations are considered extremely rare, representing only 0.2% of all dislocations, some consider this diagnosis to be underreported. High-energy trauma is the mechanism of injury; patients usually have many additional injuries and are commonly involved in polytrauma scenarios. Dislocations may be volar or dorsal, and radial translation of the carpal bones is much more common than radial translation. Emergent reduction of these injuries is paramount because of the extensive soft tissue damage and commonly associated distal neurovascular compromise. Reduction is, however, commonly difficult to maintain in these complex and unstable injuries, which usually require ORIF. Emergent orthopedic consultation in the ED is indicated.

**Distal Radius and Ulna Injuries**

Distal radius and ulna fractures remain some of the most common injuries seen in EDs worldwide. Women older than 50 years are most vulnerable and carry a 15% lifetime risk of this injury pattern. Occurring, in general, from a ground level fall on the outstretched hand in older patients and from high-energy trauma in younger patients, these injuries are commonly closed, may have intraarticular involvement and displacement, and frequently require ED closed reduction, splinting, and outpatient orthopedic referral. Plain radiographs are typically adequate for the emergent diagnosis and management of these injuries; rarely is advanced imaging indicated. A neurovascular examination should be performed to exclude any median, radial, or ulnar neurapraxia and radial or ulnar arterial compromise caused by the deformity or fracture fragments. Indications for ED reduction include significant deformity, joint subluxation, and dislocation. Postreduction radiography and a neurologic examination are recommended. Open fractures, vascular compromise, or an acute carpal tunnel syndrome are indications for emergency surgical evaluation. Open fractures should receive tetanus prophylaxis, toxoid, and immunoglobulin, as indicated, intravenous (IV) antibiotics, and surgical intervention. Numerous classification patterns have been devised, and the most commonly encountered fractures are discussed in the following sections.

**Colles’ Fracture**

Colles’ fracture, first described in 1814, is the most common wrist fracture seen in adults. It is a transverse fracture of the distal radial metaphysis, which is dorsally displaced and angulated, causing the classic dinner fork deformity seen on physical examination. The fracture usually is located within 2 cm of the radial articular surface and may be associated with comminution and intraarticular extension into the radiocarpal or radioulnar joints. There is commonly an associated fracture of the ulnar styloid in 60% to 70% of cases, which may suggest concomitant injury to the TFCC. The PA view may show extension of the fracture into the radioulnar or radiocarpal joints and the amount of intraarticular step-off and radial shortening present. The degree of dorsal displacement and angulation is best seen on the lateral view, with loss of the normal volar tilt of the distal radial articular surface (Fig. 44.24).

Many Colles’ fractures require ED reduction for restoration of radial length, correction of dorsal angulation, especially when greater than 20 degrees and, optimally, restoration of anatomic volar tilt. Closed reduction should be attempted by the emergency clinician using procedural sedation, local or regional anesthesia, or a combination of these options, followed by splint immobilization. Splinting should immobilize the wrist and allow for finger movement. Immediate circumferential casting, as well as overly tight splinting, should be avoided for at least 24 hours because edema from this injury may induce subsequent pain or neurovascular compromise. This treatment may be definitive and, if successful, allows for outpatient orthopedic referral in most cases. Methods of local and regional anesthesia for distal radial fracture reduction include the classic hematoma block, IV regional anesthesia, known as the Bier block, and regional nerve blocks, including median, radial, ulnar, and brachial plexus approaches. The hematoma block remains an easy effective method of anesthesia and may be performed by placing a 22-gauge needle in the dorsum of the distal radius, withdrawing until a fracture hematoma is encountered and then instilling 5 to 10 mL of 1% or 2% lidocaine, with or without the addition of a longer acting agent such as bupivacaine (Fig. 44.25).

Of note, hematoma blocks may avoid the requirement for procedural sedation and decrease ED length of stay. For pediatric distal radial fractures, local anesthesia should not be injected into the growth plate but is otherwise indicated. Use of finger traps also is an effective means of obtaining the reduction to allow positioning for splinting (Fig. 44.26). The more comminuted and displaced the fracture, the higher the likelihood that operative reduction will be necessary. Common emergent indications for Colles’ fracture reductions include any neurovascular compromise, significant deformity, soft tissue tension, tenting of the skin, and loss of volar tilt, with significant dorsal angulation (>20 degrees). Radial inclination greater than 15 degrees, volar tilt less than 20 degrees dorsally, radial shortening (positive ulnar variance) less than 5 mm, and intraarticular step-off less than 2 mm suggest general, not absolute, adequate emergent reduction parameters. Loss of reduction will occur in many of these patients before follow-up, especially in comminuted, intraarticular fractures, and in older adults, for whom the long-term benefits of anatomic restoration appear less beneficial. The American Academy of Orthopedic Surgeons has suggested surgical fixation of fractures with more than 3 mm of shortening, 10 degrees of dorsal tilt, and intra-articular step-off of more than 2 mm postreduction.

Complications of Colles’ fractures are seen most often in older patients and those with comminution, displacement, and inadequate fracture reduction. Although radial and ulnar nerves may be compromised, median nerve injury is most common and may occur acutely from contusion, traction from displacement, transection from fracture fragments, nerve compression after closed reduction, overlying cast pressure, or secondary to acute carpal tunnel syndrome (ACTS; see later). Thus, it is important to evaluate neurologic function before and after fracture reduction.

**Smith’s Fracture**

Smith’s fracture is a transverse fracture of the metaphysis of the distal radius, with associated volar displacement and angulation. In some cases, the fracture may extend into the radiocarpal joint. On physical examination it is known as the garden spade
CHAPTER 44  Wrist and Forearm

deformity but, because displacement is opposite to that seen in Colles’ fracture, Smith’s fracture often is called a reverse Colles’ fracture. The typical mechanism of injury involves a direct blow to the dorsum of the wrist or a fall onto the dorsum of the hand resulting in extreme palmar flexion. This fracture also may be seen after a fall backward on an outstretched hand, with the forearm in supination. The patient has a swollen painful wrist, which is deformed, with fullness visible on the volar aspect. The fracture is visible on PA and lateral radiographs of the wrist, but the lateral view best shows the degree of volar displacement and angulation (Fig. 44.27).

Treatment of this fracture involves closed reduction and immobilization in a splint, as discussed earlier. Unlike Colles’ fracture, however, Smith’s fracture is much more likely to be

Fig. 44.24. Colles’ fracture. A, Posteroanterior view shows fracture and shortening of the radius, intraarticular extension, and associated ulnar styloid fracture. B, Lateral view shows typical dorsal displacement and angulation of the radial fracture known as the dinner fork deformity.

Fig. 44.25. Hematoma block. Sterile preparation of the fracture area is performed, and local anesthetic is then introduced to the hematoma that surrounds the fracture site to assist with pain control during reduction.

Fig. 44.26. Finger traps. The distal radius reduction method typically involves traction followed by manipulation facilitated by the finger traps. Ten pounds of weight are hung from the elbow at 90 degrees of flexion for approximately 10 minutes before the reduction attempt.
unstable and to require operative repair and splint reduction; it also has an increased tendency to cause neurovascular compromise, specifically median nerve compression. Urgent orthopedic referral or emergent consultation is indicated based on the severity of angulation, neurovascular compromise, or associated soft tissue complications. Delayed tendon complications, including extensor pollicis longus entrapment and rupture, have been documented. Similarly, prognosis is most favorable in patients with successful reduction and restoration of the normal radial length and volar tilt.

**Barton’s Fracture**

Barton’s fracture is an oblique intraarticular fracture of the rim of the distal radius, with displacement and dislocation of the carpus along with the fracture fragment. The fracture may involve the dorsal rim of the radius with dorsal carpal subluxation (classic Barton’s fracture), or may involve the volar rim with volar carpal subluxation (volar Barton’s fracture). These fractures are rare and account for only 1% of all distal radius fractures. The volar-anterior margin fracture is seen more often than the dorsal-posterior margin fracture.

The mechanism of injury for these fractures is a high-velocity impact across the articular surface of the radiocarpal joint, with the wrist in volar flexion (causing a volar rim fracture) or dorsiflexion (causing a dorsal rim fracture). Volar and dorsal rim fractures are easily visible on PA and lateral wrist radiographs; however, the lateral view best shows the degree of articular surface involvement and amount of associated fracture displacement (Fig. 44.28).

Treatment of these unstable fractures requires emergent orthopedic consultation for reduction and fixation. Closed reduction may be successful when performed under fluoroscopy, although most fractures require percutaneous pinning or ORIF to restore

---

**Fig. 44.28.** Volar Barton’s fracture. Lateral radiograph of the wrist shows typical oblique intraarticular fracture of the volar rim of the radius, with associated displacement of the distal radial fragment and carpus dislocation.
Hutchinson’s Fracture

Hutchinson’s fracture, or chauffeur’s fracture, is an intraarticular fracture of the radial styloid. The mechanism of injury is usually a direct blow or fall resulting in trauma to the radial side of the wrist. The term chauffeur’s fracture originated in the era of hand-cranked automobiles, when this injury occurred because of direct trauma to the radial side of the wrist from the recoil of the motor crank. The fracture is seen best on the PA view of the wrist as a transverse fracture of the radial metaphysis, with extension through the radial styloid into the radiocarpal joint.

Nondisplaced fractures may be immobilized in a sugar tong splint, with the patient given urgent orthopedic referral; definitive treatment is in a short arm cast. However, displaced fractures, which are frequently associated with scapholunate ligament disruption, require open or closed reduction and fixation (Fig. 44.29). Because the radial styloid is the primary site of attachment for many of the ligaments of the wrist, accurate fracture reduction and union are crucial for wrist function. Posttraumatic arthritis is a common complication of radial styloid fractures and more common with displacement and scapholunate ligament disruption.

Distal Radioulnar Joint Disruption

Acute dislocation of the DRUJ can occur as an isolated injury, which is rare, or in association with a fracture to the distal radius (Colles’ fracture), radial diaphysis (Galeazzi’s fracture), or radial head (Essex-Lopresti injury). Diagnosis often is difficult because when the injury occurs in isolation or is not suspected, plain radiographs commonly are reported as normal. Certain characteristic findings on clinical examination may constitute the only clue to the presence of this injury.

The typical mechanism of injury is a fall on the outstretched hand with hyperpronation, resulting in dorsal dislocation, or hyperpronation, causing volar dislocation of the ulna. Dorsal ulna dislocations are more common than volar dislocations. Another mechanism known to cause DRUJ dislocation is the catching of the hand in rotating machinery, resulting in the same forcible hyperpronation or supination. This forcible rotation of the wrist causes disruption of the TFCC, the major stabilizer of the DRUJ, and may result in an associated avulsion fracture of the ulnar styloid.

Patients with this injury have a history of sudden onset of pain with a snapping sensation in the wrist, swelling, and limited range of motion. On examination, tenderness is present over the ulnar aspect of the wrist, with palpable crepitus on supination and pronation. With a dorsal dislocation of the ulna, the ulnar styloid appears more prominent than on the unaffected side, and significant pain and limitation of movement are noted on supination of the wrist. With a volar dislocation of the ulna, there is loss of the normal ulnar styloid prominence, with pain and limitation of movement on pronation. These characteristic clinical findings should alert the emergency clinician to the possibility of DRUJ disruption and prompt the appropriate investigations to confirm the presence or absence of injury.

Well-positioned lateral radiographs of the wrist may show the presence of a DRUJ dislocation with more than 20 degrees of dorsal angulation or volar displacement, but pain and inability of the patient to rotate the wrist fully may cause a false-negative result because a true lateral view cannot be obtained. Fractures of the ulnar styloid base may increase suspicion regarding a DRUJ disruption. It also is important to assess for radial head fractures because this injury is commonly associated with DRUJ disruption and interosseous membrane rupture (see below, “Essex-Lopresti Lesion”). A DRUJ dislocation is seen on the PA view of the wrist showing significant overlap or widening of the distal radius and ulna (Fig. 44.30). If there is significant clinical suspicion of injury, and the radiographic appearance is normal, a CT scan may assist in the diagnosis.

Treatment of these injuries commonly requires orthopedic consultation for reduction and stabilization. Closed reduction with the forearm in supination followed by application of a long arm cast often is successful. Alternatively, open reduction frequently is necessary with volar dislocations because the ulnar head often is locked on the distal radius. Operative reduction also is necessary in dorsal dislocations to repair the associated injury to the TFCC. Immobilization in a long arm cast is maintained for 6 weeks.

SOFT TISSUE INJURIES OF THE WRIST

Carpal Tunnel and Acute Carpal Tunnel Syndrome

Carpal tunnel syndrome (CTS) is the most common entrapment neuropathy; it occurs at the wrist and results in compression of the median nerve. CTS is typically a chronic, progressive, repetitive overuse syndrome and has an overall lifetime incidence around 5%, with a female preponderance. The transverse carpal ligament and volar surfaces of the carpal bones form the carpal tunnel. It is a rigid compartment that contains nine flexor tendons (flexor pollicis longus, four flexor digitorum superficialis, and four flexor digitorum profundus tendons) and the median nerve. CTS also can be associated with numerous systemic conditions, such as rheumatoid arthritis, hypothyroidism, diabetes mellitus, renal failure, congestive heart failure, acromegaly, and collagen vascular diseases. Each of these systemic diseases is thought to produce an increase in pressure within the carpal...
tunnel from thickening of the flexor synovia or transverse carpal ligament. Hormonal changes associated with pregnancy and menopause also are known to cause CTS, probably from retention of fluid in the soft tissues about the wrist.\textsuperscript{56}

The classic symptoms include a gradual onset of numbness, paresthesia, and pain in the median nerve distribution (thumb, index, long and radial aspect of the ring finger; see Table 44.1). These symptoms often are bilateral and are worse during the night and after strenuous activities. Typically, patients report numbness and paresthesias on awakening that lessens when the hands are shaken or held in a dependent position. Pain may actually radiate proximal to the carpal tunnel, and symptoms may progress to include decreased grip strength, hand clumsiness, thenar atrophy, and trophic ulceration of the fingertips.\textsuperscript{54} The differential diagnosis includes cervical radiculopathy and Raynaud’s syndrome.

The most common provocative test supporting the diagnosis of CTS is the wrist flexion or Phalen test (Fig. 44.31).\textsuperscript{23} This test is performed by asking the patient to flex the wrists fully for 60 seconds while holding the forearms in a vertical position. The test result is positive if paresthesia or numbness develops in the median nerve distribution. Other tests suggesting CTS are weakness observed on thumb abduction testing and Tinel’s sign, which demonstrates pain or paresthesias elicited by light tapping or percussion over the median nerve at the wrist. Durkan’s test, or the median nerve compression test, consists of the application of pressure directly over the median nerve at the carpal tunnel and may have the highest sensitivity and specificity for disease. However, no physical examination maneuver is completely reliable in making the diagnosis and is therefore more supportive when used in combination.\textsuperscript{54}

Nerve conduction studies have traditionally been used to confirm the diagnosis. MRI and ultrasound are also being used for confirmation, but emergently the diagnosis of CTS is primarily clinical.\textsuperscript{54}

Conservative (nonoperative) treatment for CTS yields variable results. Specific measures include splinting the wrist in a neutral position and administering cortisone injections in the carpal tunnel.\textsuperscript{54,59} Splinting initially may be prescribed full time and then reduced to immobilization at night only. Five factors that lessen the likelihood of successful nonoperative treatment are (1) age older than 50 years, (2) symptom duration longer than 10 months, (3) constant paresthesias, (4) stenosing flexor tenosynovitis, and (5) positive Phalen’s test result at less than 30 seconds. Nonsteroidal antiinflammatory drugs (NSAIDs) have proved to be of little benefit. Open or endoscopic surgical release of the flexor retinaculum to unroof the carpal tunnel is indicated when medical management fails.\textsuperscript{60}

ACTS, which occurs over hours rather than weeks, months, or years, is much less common than the chronic, gradually progressive presentations of CTS requiring symptomatic relief, appropriate referral, and patient education. ACTS is more often directly related to fractures, fracture-dislocations, hemorrhagic conditions, infections, vascular disorders, and edema involving the wrist. Although the carpal tunnel is open at both ends, it has the physiologic properties of a closed compartment.\textsuperscript{56} Distal radius fractures are likely the most common cause of ACTS; however, lunate and perilunate dislocations are associated, and even isolated carpal fractures and rupture of the EPL tendon have been documented as rare causes. Trauma resulting in an ACTS is typically relieved by closed reduction, and no reliable clinical method currently exists for differentiating acute median nerve compression in ACTS from concussive insult. In the absence of trauma, ACTS has occurred secondary to hemorrhagic, vascular and bleeding disorders and anticoagulant use. When ACTS has been diagnosed, orthopedic consultation is recommended for surgical decompression and release of the transverse carpal ligament.

**de Quervain’s Disease and Intersection Syndrome**

De Quervain’s disease and intersection syndrome, like CTS, have been grouped into the overuse or repetitive strain injury pattern category, sometimes referred to as work-related cumulative trauma in the occupational medical literature. The APL and EPB, both within the first dorsal extensor compartment of the wrist, are the tendons affected in de Quervain’s disease. Traditionally known as a stenosing tenosynovitis, tendinitis, or tendovaginitis of the wrist, de Quervain’s disease involves enlarged tendons, which may reach five times their original size, creating a stenosing tendinopathy. Clinically, patients report pain on the radial side of
the wrist, with ulnar deviation, thumb movements, weakened grip strength, or a combination of these symptoms. Onset is gradual and typically the result of increased use. There are no large epidemiologic studies, but de Quervain’s disease is thought to be common, affecting women six times more frequently than men, typically at an age older than 40 years. Radiographs are useful in ruling out bony pathology, but the diagnosis may be made with physical examination only. Originally described in 1930, Finkelstein’s test has long been considered to be a pathognomonic sign of de Quervain’s disease.67

There are surprisingly few prospective randomized controlled studies with good methodologic quality regarding treatment of de Quervain’s disease. Conservative interventions of rest, splinting, and NSAIDs are the first-line treatments for mild to moderate disease. Wrist splints with thumb spicas effectively immobilize the APL and EPB, but pain may return when initiating activity is resumed. As a result, ED management should consist of rest, splint immobilization, and anti-inflammatory doses of an NSAID, if not contraindicated. Injection of corticosteroid preparations into the dorsal extensor compartment of the wrist may be offered at follow-up with an orthopedic surgeon, rheumatologist, or primary care physician. Patients with refractory or severe cases of de Quervain’s disease that interfere with activities of daily living undergo surgical release of the first dorsal extensor compartment of the wrist, with decompression of the APL and EPB tendons.

Intersection syndrome is another overuse tendinopathy that clinically manifests with pain on the radial side of the wrist, approximately 4 to 8 cm proximal to the site of de Quervain’s disease. The condition is also known as peritendinitis crepitans or crossover or oarsman’s syndrome. The mechanism of injury is secondary to rowing, weightlifting, or a repetitively resisted pulling action. Pathophysiologically, intersection syndrome occurs secondary to inflammation where the muscle bellies of the APL and EPB cross over the muscle bellies of the extensor carpi radialis longus and brevis proximal to the retinaculum. Physical examination findings include significant pain, soft tissue swelling, and crepitus with movement in more severe cases. Ultrasound findings may include thickened tendons or effusion, and radiographs are negative. The treatment for this disease is immobilization with a wrist splint and antiinflammatory medication, as specified for de Quervain’s disease. Although surgical treatments have been described, this syndrome is typically self-limited.68

### ANATOMY

The forearm is a unique two-bone structure with the radius and ulna being bound at both ends by a ligamentotocapsular structure. The proximal radioulnar joint (PRUJ) consists of an articulation between the radial head and ulna. The radial head, the primary stabilizer of the forearm combined with the annular, quadrate, radial, and ulnar ligaments, provides strong support at the PRUJ. At the DRUJ, the TFCC and anterior and posterior radioulnar ligaments support the articulation of the distal radius and ulna.69 The interosseous membrane further stabilizes the forearm by providing a strong interconnection between the radius and ulna. The ulna is relatively straight and provides the rotational axis for the bowed radius to rotate around through various planes of motion. The supinator, pronator teres, and pronator quadratus muscles insert along the shaft of the radius and ulna to provide their named function, but they also are responsible for the deforming forces in forearm fractures.

The forearm is typically divided into three compartments—volar, dorsal, and mobile wad. The interosseous membrane divides the volar and the dorsal compartments, and the mobile wad is located laterally (Fig. 44.32). The volar compartment, which can be further divided into superficial and deep layers, contains the pronators and flexor muscles of the hands. The radial, ulnar, and anterior interosseous arteries and median, ulnar, and superficial radial nerves are also contained within the volar compartment. The dorsal compartment consists of the extensor muscles of the hand and posterior interosseous artery and nerve. The mobile wad is located in the proximal lateral aspect of the forearm and contains the brachioradialis, extensor carpi radialis longus, and extensor carpi radialis brevis.

### CLINICAL FEATURES

Obtaining the history of the mechanism of injury is crucial in the initial assessment of a forearm injury. The most common mechanism of injury is an axial load applied to the forearm through the hand, which often leads to rotational displacement. Patients may present with obvious deformity and a significant amount of pain.

Physical examination of the forearm injury begins with visual inspection by evaluating for swelling along the injured area, obvious deformity, and evidence of lacerations. Gentle palpation can assist in localization of the injury; reveal crepitus in grossly unstable fractures, and allow assessment of skin turgor in the evaluation of compartment pressure. Significant swelling, as well as disproportionate pain, paresthesia, and paleness of skin, should alarm emergency clinicians regarding the development of compartment syndrome. Neurologic evaluation should include careful examination of motor and sensory function of the radial, ulnar, and median nerves. Assessment of the brachial, radial, and ulnar arteries should be part of the vascular examination. Please see pediatric fractures and compartment syndromes referenced within this text.

### Diagnostic Testing: Radiology

The radiologic evaluation of the forearm injury should begin with the AP and lateral views. It is essential to include wrist and elbow in the x-ray examination of the forearm to exclude any concomitant injuries to the DRUJ or PRUJ.

On the normal AP view of the forearm, a medially pointing radial styloid and laterally projecting biceps tuberosity of the proximal radius are visible. On the lateral view, the coronoid process of the proximal ulna points volarly, and the ulnar styloid lies dorsally (Fig. 44.33). Any deviation suggests an abnormal rotational or axial deformity. The normal radiologic findings of the forearm, including radiocarpal articulation angle, relationship

### Principles

Forearm injuries are common encounters in the ED. There is a bimodal age distribution of patients who suffer forearm injuries—children aged 6 to 15 years and adults older than 50 years. In children, forearm fractures account for nearly 50% of all pediatric fractures and are on the rise due to an increase in sports activity and body mass index (BMI).64 Please refer to pediatric fractures referenced within this text.

Mechanisms of injury for forearm fractures include falls on outstretched hands, direct blows to the area, or high-energy trauma, such as involvement in a motor vehicle collision. Evaluation of forearm injuries requires an understanding of the independent biomechanical relationship between the radius and ulna. These two bones articulate at the proximal and distal ends, which allows the radius to rotate around the ulna to provide pronation and supination. Because fracture of the radius or ulna can result in dislocation at the wrist or elbow, emergency clinicians should be vigilant when treating forearm fractures. Early diagnosis and prompt treatment of these injuries are critical to prevent loss of function.
between radial styloid and ulnar styloid, and normal volar tilt of the radius, are described in the section on radiology of the wrist (see earlier).

Injury to the radial head can be evaluated by drawing a midaxis line through the radial shaft, neck, and head. This radial midaxis line should intersect the center of capitellum of the elbow on any radiologic view. Any variance from this alignment should raise suspicion regarding radial head dislocation (Fig. 44.34).

CT scans can be useful when there is a suspicion of extension of the fracture into the DRUJ or PRUJ on plain radiography. MRI is the study of choice for evaluation of soft tissues (eg, muscle, tendon, ligament) of the forearm, including the interosseous membrane. Ultrasound images can also help with evaluation of interosseous membrane injury and to determine when pediatric forearm fractures have been adequately realigned after closed reduction.

**MANAGEMENT AND DISPOSITION**

**Forearm Injuries**

**Shaft Fractures of Radius and Ulna**

Fractures involving both the radius and ulna, also known as both bone fractures, are common forearm injuries. Patients often have pain and obvious deformity of the forearm as a result of minor or major trauma. Careful physical examination is warranted to exclude any associated neurovascular injury or open fracture. Compartment syndrome should be considered in all patients with this type of injury. The initial radiologic evaluation should include not only AP and lateral radiographs of the forearm, but also dedicated wrist and elbow radiographs.

After initial evaluation, any open fractures should be irrigated with sterile normal saline to decrease contamination, and a sterile dressing should be applied, along with parental antibiotics, while awaiting operative management. Any grossly displaced fracture-dislocation should be reduced to improve alignment and prevent impending or ongoing neurovascular injury. Application of a sugar tong forearm splint should be made with an urgent referral to an orthopedist, as long as there is no evidence of open fracture or neurovascular compromise.

Because nondisplaced radius and ulna fractures are extremely uncommon, most both bone fractures of the forearm in adults will require operative management. Common complications of combined radius and ulna fractures are nonunion, malunion, infection, and neurovascular injury.

**Ulna Shaft Fractures**

Isolated fractures of the ulna shaft, known as nightstick fractures, are seen frequently in the ED. Patients often have pain and swelling over the medial aspect of the forearm, because the usual
mechanism involves raising the arm overhead to protect it from a direct traumatic impact. Careful inspection of the skin is necessary; many patients have open fractures, given the superficial position of the ulna directly under the subcutaneous skin. The complete examination should include wrist and elbow examinations to exclude any associated injuries involving the PRUJ or DRUJ. The emergency clinician should be aware of potential instability at either articulation associated with fractures involving the proximal or distal third of the ulna.

Diagnosis of an ulna fracture is made through the findings on AP and lateral radiographs of the full-length forearm (Fig. 44.35). Although most isolated ulna fractures are considered stable, those with more than 50% displacement, more than 8 degrees of angulation, involvement of the proximal third of the ulna, or instability at the DRUJ or PRUJ are considered unstable fractures. There are no absolute indications for operative management of isolated ulna shaft fracture; however, unstable fractures should be referred to an orthopedist urgently for possible ORIF because they carry a high risk of function loss, nonunion, malunion, and radioulnar synostosis.

Monteggia’s Fracture

The ulna fractures associated with radial head dislocation are commonly known as Monteggia’s fractures. In 1814, Giovanni Battista Monteggia specifically described a traumatic lesion involving the fracture of the proximal third of the ulna and anterior dislocation of the radius. In 1974, Bado redefined Monteggia’s lesion and classified it to encompass various ulna fractures with concomitant radial head dislocation. The Bado classification divides the injury into four types depending on the location and angulation of the ulna fracture, along with the direction of the radial head dislocation.
Patients with Monteggia's fracture often have fallen on an outstretched hand, resulting in hyperpronation. Direct posterior force on the ulna or a fall on the flexed elbow has also been implicated in the mechanism of the injury. Typically, patients have swelling and tenderness along the fracture site accompanied by a limited range of motion at the elbow and pain with pronation of the forearm. A dislocated radial head may be appreciated on palpation. Initial assessment of Monteggia's fracture should include complete neurologic examination because the posterior interosseous nerve (PIN), a deep branch of the radial nerve, can be injured. Because the PIN innervates the finger extensors along with the supinator, PIN injury is often manifested by weakness or paralysis of the thumb and/or finger extension.

The radiograph of the forearm reveals the obvious ulna fracture that often overshadows the subtle radial head dislocation (Fig. 44.36). A chronic, irreducible radial head dislocation can occur as a result of delay in diagnosis. Drawing the radiocapitellar line (RCL) through the head of the capitellum can prevent overlooking a proximal dislocation. The line should intersect the distal third of the capitellum on all views and confirm correct alignment. However, in young children, an RCL may not reliably bisect the capitellum in normal pediatric patients. An abnormal RCL should be suggestive of but not pathognomonic for an injury.

Treatment of Monteggia's fracture depends on the age of the patient. Pediatric patients with this type of injury can be treated conservatively, with long arm casting in supination with acceptable reduction. However, most adult patients with this type of fracture should be referred to an orthopedic surgeon urgently for ORIF. Complications of Monteggia's fracture include malunion, nonunion, synostosis, stiffness, and nerve palsy. Early diagnosis and treatment of Monteggia's fracture are crucial in achieving good outcomes.

Galeazzi's Fracture

Galeazzi's fracture refers to a fracture of the middle to distal third of the radius associated with injury to and dislocation of the DRUJ. It accounts for 3% to 7% of all forearm fractures. Typically, Galeazzi's fracture results from a fall or motor vehicle collision as the patient attempts to brace for impact by stretching out the hand in hyperpronation. A direct blow to the dorsolateral aspect of the forearm is less common but also well recognized as a mechanism of injury for Galeazzi's fracture. Galeazzi's fracture is often overlooked as a simple radius fracture, yet it often results in diminished forearm range of motion, loss of function, weakness, and chronic pain.

In addition to radiographic imaging, the history and clinical examination play a critical role in the diagnosis of Galeazzi's fracture because injuries to the DRUJ may not be obvious. Patients with Galeazzi's fracture have deformity at the site of the fracture associated with swelling and tenderness. Meticulous attention is required in examining the wrist to evaluate for stability of the DRUJ. Instability of the DRUJ can range from obvious prominence of the ulnar head (associated with the subluxation or dislocation) to tenderness elicited at the wrist, which can be a subtle sign of DRUJ ligament injury.

AP and lateral radiographs of the entire forearm and wrist are essential to diagnose Galeazzi's fracture. Besides the obvious fracture of the radius at the middle to distal third, there will be other radiographic findings. On the AP view of the forearm, the space between the distal radius and ulna is widened (>2 mm) and the radius appears relatively shortened. In the lateral view, the dorsally angulated fracture of the radius can cause a dorsal displacement of the ulnar head. A fracture at the base of the ulnar styloid should raise the suspicion for DRUJ disruption (Fig. 44.37). Although not all radius shaft fractures are associated with DRUJ injury, previous studies have shown that at least 25% of all patients with radius fractures have DRUJ dislocation. Therefore, patients with radius shaft fractures should be referred to an orthopedist for close follow-up.

Conservative management of Galeazzi's fracture in adults has been associated with poor outcomes. Due to deforming forces from different forearm muscles and loss of stability at the DRUJ, displacement of the alignment in the cast occurs, despite successful initial reduction. Galeazzi's fracture has been termed a fracture of necessity to imply that surgical intervention is pivotal for achievement of an ideal anatomic position and acceptable functional outcomes. Any skeletally matured patients with this fracture should be referred to an orthopedist urgently for ORIF of the radius and associated repair of the DRUJ. In contrast, conservative treatment with closed reduction and long arm casting has been successful in children and rarely necessitates surgical

Fig. 44.36. Monteggia's fracture-dislocation. A fracture of the ulna diaphysis with anterior dislocation of the radial head (arrow) is shown in this lateral view of the forearm.

Fig. 44.37. Galeazzi's fracture-dislocation. The anteroposterior (A) and lateral (B) views of the forearm show an obvious fracture of the distal third of the radius, with severe displacement and an associated dislocation of the distal radioulnar joint (arrow).
intervention. Along with the common complications associated with forearm fractures, such as malunion and nonunion, the occurrence of subluxation and dislocation of the DRUJ can result in limited motion and chronic pain.

Essex-Lopresti Lesion

The Essex-Lopresti lesion, or longitudinal radioulnar disassociation, refers to an unstable forearm as a result of a triad of injuries to the radial head, disruption of the interosseous membrane, and violation of the DRUJ. The patient often has fallen on an outstretched hand, resulting in transmission of a large axial loading force from the wrist to elbow. Consequently, the radial head, the primary forearm stabilizer, is fractured and displaced proximally. Disruption of the interosseous membrane and DRUJ also occurs and compromises the stability of the forearm. In addition to localized pain along the elbow from a radial head fracture, patients with the Essex-Lopresti lesion have wrist and forearm pain, along with grip and pronation weakness.

The diagnosis of Essex-Lopresti lesion remains elusive because the standard AP and lateral views of the forearm often reveal only an isolated radial head fracture. Thus, the incidence of the lesion may be higher than previously appreciated. The integrity of the interosseous membrane is difficult to assess based on a plain film. Subtle findings of positive ulna variance and a widened DRUJ are suggestive of longitudinal radioulnar dissociation. Obtaining a grip view and comparing the injured wrist with the contralateral wrist can be helpful in diagnosing an Essex-Lopresti lesion. MRI is the study of choice when clinical suspicion for an Essex-Lopresti lesion is high; however, ultrasound has recently been used more frequently to evaluate the integrity of the interosseous membrane.

Once the diagnosis of Essex-Lopresti lesion has been made, the patient should be referred to an orthopedic surgeon for further surgical intervention. Many strategies have been proposed to repair Essex-Lopresti lesions, and the treatment option varies, depending on the chronicity of the injury. Radioulnar synostosis and loss of forearm rotation can result from longitudinal disassociation.

KEY CONCEPTS

- On the PA radiograph of the wrist, three arcs, known as Gilula’s lines, and equal spacing between carpus bones (1–2 mm), known as parallelism, assist in the radiographic diagnosis of carpal injury.
- In the setting of acute trauma, there is a high incidence of occult fractures and soft tissue injuries of the wrist. Because of the associated risk of malunion, nonunion, posttraumatic arthritis, and AVN if diagnosis is delayed, splint immobilization is recommended when radiographs are negative and pain persists. A thumb spica is usually added in the setting of suspected scaphoid and other carpal fractures. Follow-up for repeat physical examination, radiographs, or advanced imaging (eg, MRI, CT, or bone scan) is indicated.
- Routine wrist radiographs (AP, lateral, and oblique projections) fail to detect 15% of scaphoid fractures. Approximately one in four (25%) of splinted patients will subsequently be diagnosed with a scaphoid fracture.
- Triquetral dorsal chips are best seen on the standard lateral view of the wrist as a small avulsion fracture fragment, although a more oblique pronated lateral view may be necessary to visualize it.
- Hamate and pisiform fractures are better visualized with a carpal tunnel or reverse supinated oblique radiograph.
- Lunate dislocation results in a characteristic triangular appearance of the lunate on the PA view (so-called piece of pie sign) owing to rotation of the lunate in a volar direction. This rotation also is visible on the lateral view of the wrist, on which the lunate looks like a cup tipped forward and spilling its contents into the palm (spilled teacup sign).

ACKNOWLEDGMENT

We would like to thank Karen G.H. Woolfrey, Michael Woolfrey, and Mary A. Eisenhauer for their contributions to previous versions of this chapter.

REFRENCES

44.1. In the setting of acute trauma and negative radiographs of the wrist, which clinical examination method(s) is (are) used to detect occult scaphoid fractures?

A. All of these  
B. Anatomic snuffbox tenderness  
C. None of these  
D. Scaphoid tubercle tenderness  
E. Thumb metacarpal compression tenderness

**Answer**: A. In the setting of acute trauma and negative radiographs, tenderness to palpation within the anatomic snuffbox, on the scaphoid tubercle, or with thumb metacarpal compression are all suggestive of occult scaphoid fracture.

44.2. A 45-year-old man complains of wrist pain after falling on an outstretched hand. What injury is shown in this radiograph of the patient’s wrist?

A. Barton’s fracture  
B. Lunate dislocation  
C. Perilunate dislocation  
D. Scaphoid fracture  
E. Scapholunate dissociation

**Answer**: E. The radiograph shows the signet ring, or cortical ring sign, which refers to the rotary subluxation of the scaphoid and oval appearance of the tubercle in the anteroposterior (AP) view of the wrist. On a properly positioned radiograph, this sign is typically associated with scapholunate widening, suggesting ligamentous laxity or dissociation. The signet ring sign is also used to describe pulmonary computed tomography (CT) imaging of bronchiectasis in relation to a dilated bronchus and associated pulmonary artery.

44.3. A 55-year-old man complains of wrist pain after a fall onto an outstretched arm. There is pain and swelling along the carpal bones. Also noted is decreased two-point sensation distally on the tips of the index and middle digits. Which structure is most likely injured?

A. Median nerve  
B. Radial artery  
C. Radial nerve  
D. Ulnar artery  
E. Ulnar nerve

**Answer**: A. The median nerve courses through the carpal tunnel on the ventral aspect of the wrist. It provides sensation to most of the palm and thumb, half of the ring finger and, specifically, the tips of the index and middle digits. The median nerve is the most common neurapraxia associated with Colles’ fractures.

44.4. Which nerve is commonly associated with Monteggia’s fracture?

A. Muscular branch of the radial nerve  
B. Posterior interosseous nerve  
C. Deep branch of the ulnar nerve  
D. Median nerve  
E. Ulnar nerve

**Answer**: B: Injury to the posterior interosseous nerve (PIN), a deep branch of the radial nerve, is commonly associated with Monteggia’s fracture. Because the PIN innervates the finger extensors along with the supinator, associated injury is often manifested by weakness or paralysis of the thumb and/or finger extension.
CHAPTER 45

Humerus and Elbow

Kelly Bookman*

PRINCIPLES

Injuries in the region of the elbow can be difficult to diagnose and have a high potential for complications and residual disability. Recognition of neurovascular and soft tissue complications improves the outcome in many of these injuries. Knowledge of the relevant anatomy, mechanisms of injury, and appropriate management techniques, as well as knowing when to refer to or consult with orthopedic specialists will improve outcomes. The essential anatomy of the elbow region, as it relates to acute injury, is shown in Figures 45.1 to 45.4.

CLINICAL FEATURES

History includes a description of the mechanisms of any traumatic event, pain characteristics including quality, duration, location, effects of movement, exacerbating or alleviating factors, severity, and radiation, in addition to concomitant injury or systemic complaint. Past medical history should include occupational factors and prior or chronic problems with the affected joint or other bones or joints. Numbness or weakness distal to the injury may indicate neurovascular injury. Pediatric orthopedic injuries, including those caused by abuse, are discussed in Chapters 165 and 177.

Examination begins with simple inspection and comparison with the contralateral limb. The position in which the extremity is held should be noted. Deformity may indicate fracture, dislocation, or hematoma. Range of motion may be evaluated, depending on the appearance of the extremity and suspicion of injury, but general manipulation of the acute injured extremity should be minimized gently. Bony prominences are palpated with notation of specific areas of tenderness. Crepitus, bony deformity, and pain in an acutely injured limb are virtually diagnostic of a fracture. The radial head specifically is palpated for tenderness. Intra-articular elbow fractures, including those of the radial head, are universally associated with effusion (hemarthrosis). Elbow effusion is notoriously difficult to discern on examination but is readily identified on lateral radiographs (Fig. 45.5). The extremity also should be inspected for swelling, compromised circulation, or any wound that may indicate an open fracture.

In addition to the elbow region itself, examination incudes thorough evaluation of the distal neurovascular status of the extremity. The vascular status of the extremity is of highest priority. Presence of the brachial, radial, and ulnar pulses is confirmed by palpation. The ulnar pulse is more difficult to palpate than the radial pulse and is not palpable in some normal people. Although a warm hand with normal color suggests adequate tissue perfusion, a handheld Doppler device often is required to evaluate major vessel flow if significant swelling is present or if the pulses are not palpable. Poor perfusion may result from direct arterial injury, compression or kinking in the instance of significant displacement from a fracture or dislocation, or compartment syn-

* I would like to thank Thom Mayer, Joel M. Geiderman, and Sam S. Torbabi for their work on this chapter in previous editions.

drome. Identification of arterial compromise or injury warrants consultation with an orthopedic or vascular surgeon (see Chapter 41). Compartment syndrome is discussed in Chapter 42. Orthopedic consultation and measurement of compartment pressures is indicated for patients who are suspected of compartment syndrome. The radial, median, and ulnar nerve all transit the elbow in close proximity to major bony structures, so their motor and sensory functions require careful evaluation. The radial nerve can be tested by evaluating sensation to the dorsum of the hand and wrist extension. The median nerve should be tested for sensory function by assessing sensation at the lateral aspect of the thumb and for motor function by having the patient perform an “okay” sign. The ulnar nerve serves the sensation of the palmar aspect of the fifth digit and motor function to the medial interosseous muscles, which can be tested by having the patient abduct the small finger from the ring finger against pressure.

When movement of the elbow is possible without significant pain, the range of motion of the elbow in all planes (ie, flexion-extension and pronation-supination) is determined. Inability to tolerate even minimal passive movement often indicates dislocation or severe fracture. With the forearm supinated, the normal range of motion is 0 degrees in full extension to 150 degrees in full flexion. A mild degree of hyperextension is normal in some individuals and should be symmetrical. With the elbow flexed at 90 degrees and the thumb facing up, the forearm normally supinates and pronates 90 degrees. Range-of-motion testing may be limited by pain and impossible with severe injuries and can be postponed until after radiographic evaluation.

Most elbow and humerus injuries are evaluated radiographically, although on occasion history and clinical examination alone are sufficient to make a diagnosis (eg, minor mechanism fall with minimal pain, full range of motion, and no significant bony tenderness). There are no validated clinical decision rules for the elbow, so radiography should be performed when there is moderate to severe pain, significant limitation in range of motion, obvious deformity, swelling or effusion, or significant tenderness over any of the bony prominences or the radial head. With the exception of children with obvious nursemaids’ elbow (radial head subluxation), radiography should be used in virtually all pediatric elbow injuries with any bony tenderness on examination to assess for possible growth plate injury.

Routine views of the elbow include at least the anteroposterior and lateral views, with oblique views when necessary. Anteroposterior and oblique views are taken with the elbow extended. The lateral view is taken with the elbow in 90 degrees of flexion and the thumb pointing upward. Positioning of the elbow is important because anything but a true lateral view makes accurate interpretation of soft tissue findings and alignment difficult.

Most fractures in the elbow region are identifiable on plain film, but radial head and subtle supracondylar fractures may be difficult to visualize, and examination of the fat pads to identify effusion reduces the risk of missing them. The normal cortex of the radius is smooth and has a gentle continuous concave sweep. If consistent with history and physical findings, any disruption of this smooth arc is considered evidence of fracture. Abnormalities
within the soft tissues on elbow films are particularly important and may be the only radiographic sign of a fracture. Normally, fat surrounding the proximal elbow joint is hidden in the concavity of the olecranon and coronoid fossae. The normal elbow has only a narrow strip of lucency anteriorly, parallel to the anterior surface of the distal humerus (the anterior fat pad), and there is no posterior fat pad. Injuries that produce intra-articular hemorrhage cause distention of the synovium and displace the fat out of the fossa, making the posterior fat pad visible on lateral radiographic views. This intra-articular swelling displaces the anterior fat farther anteriorly, where it takes the shape of a sail from a boat. The radiographic finding is commonly referred to as the “sail sign.” Displacement of the posterior fat pad makes it visible on the lateral radiograph as a “posterior fat pad sign” (see Fig. 45.5). In the setting of trauma, more than 95% of patients with the “posterior fat pad” sign have intra-articular skeletal injury. These soft tissue findings occur even with subtle fractures, and when present in the setting of trauma, an occult fracture is considered to be present. In adults without an identifiable fracture on radiograph, fat pad signs most often indicate a radial head fracture, whereas in children a supracondylar fracture is the more likely underlying injury. In the absence of trauma, the presence of a fat pad suggests other causes of effusion (eg, inflammation, infection). The fat pad sign may be absent in fractures where the injury is severe enough to rupture the capsule.

**DIFFERENTIAL DIAGNOSIS**

Injuries in the region of the shaft of the humerus and about the elbow fall into several categories including fractures, dislocations/subluxations, and soft tissue disorders (Table 45.1).
Fractures

Shaft of the Humerus

Clinical Features. Fractures of the humeral shaft commonly result from a direct blow to the arm, severe twisting, or a fall on an outstretched hand. Rarely, fractures may be caused by violent muscle contraction, such as occur when a javelin or baseball is thrown. The shaft of the humerus most commonly fractures in the middle third in a transverse fashion. The patient reports localized pain, which is often severe in nature, and the arm is visibly swollen and cannot be used. When a fracture is complete, bony crepitus is felt in the shaft of the humerus with any manipulation of the arm. The arm may be shortened or rotated, depending on the displacement of the fracture fragments. When the fracture is incomplete, there is bony tenderness and swelling without obvious deformity.

Diagnostic Testing. Studies routinely should include the shoulder and elbow joints. The humerus is a common site for benign tumors, unicameral cysts, and primary bone malignancies, as well as a common site for metastatic disease. Thinning of the cortex and abnormal osteoblastic or osteoclastic activity are evidence of a pathologic fracture (Fig. 45.6). These fractures do not heal without concomitant treatment of the underlying pathologic condition.

Management. Isolated, closed fractures are treated conservatively with a high degree of success. Attempts at fracture reduction and external immobilization are unnecessary and sometimes detrimental to healing. Fractures that are nondisplaced or minimally displaced are immobilized by adding a coaptation, or “sugar-tong” splint, to the sling and swathe (Fig. 45.7). The coaptation splint is often replaced by a functional brace after the first 10 to 14 days. If the fracture is grossly displaced or comminuted, the hanging cast technique is preferable. This technique is especially effective with spiral fractures (Fig. 45.8). Care is taken not to make the cast too heavy because this would distract fracture fragments. The hanging cast has the disadvantage of using gravity for traction and requires that the patient remain upright at all times, including during sleep, a situation that many patients find intolerable. Neurovascular examination should be repeated and documented before and after the application of any splint or cast because loss of nerve function from entrapment of the nerve between fragments can occur after these interventions. Open reduction and internal fixation (Fig. 45.9) is necessary for open fractures, presence of multiple injuries that preclude mobilization, bilateral fractures, poor reduction, poor patient compliance, failure of closed treatment, and fractures through pathologic bone. Although the success rate with nonoperative intervention is about 80%, patients should be included in treatment decisions regarding nonoperative versus operative intervention because operative intervention may decrease recovery time with earlier return to work. For open fractures, the wound should be covered immediately with normal saline soaked gauze. Splinting can be done for comfort during patient manipulation but should be limited. Cephalaxin (1 g intravenously) is given, and consultation is obtained by orthopedic surgery for emergent operative washout.

The most common complication, radial nerve injury, occurs in up to 25% of humerus fractures. Radial nerve injury causes wrist drop with loss of the ability to extend the fingers and thumb. This nerve injury is most often a benign neurapraxia that resolves...

### Subluxations/dischlocations

| Elbow dislocation | Posterior | Fall on the outstretched hand or wrist, the elbow being either extended or hyperextended | Elbow in flexion at approximately 45 degrees and have marked prominence of the olecranon | Obvious dislocation, must assess for concurrent fractures |
| | Anterior | Blow from behind to the olecranon while the elbow is in the flexed position | Upper arm appears shortened, the forearm elongated and supinated, the elbow is fully extended and the olecranon fossa is palpable posteriorly | Obvious dislocation, must assess for concurrent fractures |
| | Medial/lateral | Mechanism similar to that in posterior dislocations, with a vector of force displacing the ulna and radius as a unit either medially or laterally | Obvious deformity either medially or laterally | Obvious dislocation, must assess for concurrent fractures |
| | Radial head subluxation | Forearm pulled while in pronation with the elbow extended, direct blow, twisting | Arm held in passive pronation, with slight flexion at the elbow; refuses to move the arm, localized tenderness, swelling, ecchymosis and deformity are absent | Radiographs are not necessary and are rarely positive |

### Soft tissue

| Epicondylitis | Repetitive pronation and supination of the forearm | Dull pain over lateral aspect of elbow, the lateral epicondyle or radiohumeral joint, increased by grasping or twisting motions | Radiographs normal or may have calcifications |
| Olecranon bursitis | Repetitive minor trauma, inflammatory | Progressive pain, tenderness, and swelling over olecranon | None |
| Bicep tendon rupture | | | |
| Proximal | Repetitive microtrauma to the tendon | Visible defect at top of bicipital groove with bunching of the muscle distally, flexion of elbow produces pain at proximal insertion but flexion remains intact | None |
| Distal | Extension force applied to the arm flexed at 90 degrees | Pain and tearing in the antecubital region, visible deformity and palpable defect of the biceps muscle belly with weakness of elbow flexion and supination | None |
Disposition. All patients with humeral shaft fractures should be referred to an orthopedic surgeon for further evaluation within 48 hours after the ED visit to ensure that the alignment has been maintained, no neurological deficits have emerged, and pain is adequately controlled. Emergent referral to an orthopedist is recommended for patients with evidence of radial nerve injury, severely displaced or comminuted fractures, open fractures, or fractures associated with forearm fractures in the same extremity.

Distal Humerus

Supracondylar Fractures. Distal humerus fractures that occur proximal to the epicondyles are called supracondylar fractures. This type of fracture is almost exclusively an injury of the immature skeleton, with a peak incidence in children 5 to 10 years old.2 This injury rarely occurs after age 15 and accounts for approximately one half of all elbow fractures and one third of pediatric limb fractures. In children, the tensile strength of the collateral ligaments and joint capsule of the elbow is greater than that of bone. In adults, the reverse is true, and a fall or accident that would result in a supracondylar fracture in children would likely result in a posterior elbow dislocation in an adult. Supracondylar fractures are classified as either extension or flexion fractures, depending on the mechanism of injury and the displacement of the distal fragment. Of these injuries, 98% are of the extension type.

Extension Type Supracondylar Fractures

Clinical Features. Extension supracondylar fractures occur as a consequence of a fall on the outstretched hand when the elbow is either fully extended or hyperextended (eg, a fall off the “monkey bars”). The strong action of the triceps tends to pull and displace the distal fragment in a posterior and proximal direction. In children with extension-type supracondylar fractures, the arm is held at the side and has a characteristic S-shaped configuration, whereas with flexion-type supracondylar fractures, the forearm is supported with the opposite hand with the elbow flexed to 90 degrees. There may be anterior angulation of the sharp distal end of the proximal fragment into the antecubital fossa, which could injure the brachial artery and median nerve (Fig. 45.10). In most cases, however, the brachialis muscle protects the anterior neurovascular structures from injury. Because this fracture primarily

spontaneously in over 90% of cases without operative intervention, although recovery may take 6 to 9 months.1 Patients should be advised of this possible complication prior to discharge and follow-up with an orthopedic surgeon should be arranged before the patient leaves the emergency department (ED). Exploration and internal fixation are indicated if the radial nerve palsy develops after manipulation, because this is highly suggestive of nerve entrapment.2 Radial nerve injuries associated with penetrating trauma or open fractures are likely to be caused by anatomical nerve disruption and usually warrant operative exploration. Median and ulnar nerve injuries are rare and usually secondary to penetrating trauma. Injuries to the brachial artery occur rarely and, if suspected, vascular surgery consultation is indicated, often with angiography or other vascular studies.
occurs in children, 25% of supracondylar fractures are of the greenstick variety, with the posterior cortex remaining intact. Subtle changes (eg, the presence of a posterior fat pad or an abnormal anterior humeral line) may be the only radiographic clues to the presence of a fracture (Fig. 45.11). Ten percent of children lose the radial pulse temporarily, most often as a result of swelling and not direct brachial artery injury. Fracture reduction, avoiding flexing the elbow more than 90 degrees and elevating the arm help prevent secondary obstruction to arterial flow. Nerve injuries occur in 11% of these injuries, but the incidence increases to a range of 19% to 49% with increasing severity of fracture displacement. The anterior interosseous nerve is the most commonly injured, followed by the radial, median, and ulnar nerves. Most deficits seen at the time of injury are
neurapraxias that resolve with conservative management. Motor function returns within 7 to 12 weeks, whereas recovery of sensation may take more than 6 months. 6,8

**Diagnostic Testing.** Two diagnostic aids in evaluating for possible supracondylar fractures include using the anterior humeral line and evaluating Baumann’s angle. The anterior humeral line is a line drawn on a lateral radiograph along the anterior surface of the humerus through the elbow. Normally, this line transects the middle third of the capitellum (Fig. 45.12). With an extension supracondylar fracture, this line passes more anteriorly. The abnormal relationship between the anterior-humeral line and capitellum may be the only evidence of a minimally displaced supracondylar fracture and is a presumptive finding of a fracture. Baumann’s angle is the intersection of a line drawn on the anteroposterior film through the midshaft of the humerus and the growth plate of the capitellum defines an angle of approximately 75 degrees (Fig. 45.13). 9 Radiographic evaluation of the elbow in children is difficult because of the presence of multiple ossification centers (Fig. 45.14). Comparison views of the uninjured elbow are often helpful in distinguishing fractures from the normal epiphyses and ossification centers. Table 45.2 lists the typical age of first appearance and fusion of ossification centers.

Based on radiographic findings, supracondylar fractures are classified into four types: type I, minimal or no displacement; type IIA, displaced fracture, posterior cortex intact with no rotational component; type IIB, displaced fracture, posterior cortex intact with no rotational component; type III, totally displaced fracture, anterior and posterior cortex disrupted; and type IV, multidirectionally unstable due to complete circumferential periosteal disruption. 10

**Management and Disposition.** Current treatment recommendations for supracondylar fractures from the American Academy of Orthopaedic Surgeons remain based on the modified Gartland classification (Box 45.1). Nondisplaced extension supracondylar fractures (type I) are immobilized primarily for comfort...
and protection, because they are inherently stable. They are treated in a splint or cast flexed to 75 to 80 degrees with the forearm in neutral rotation. Protected active range of motion is begun in approximately 3 weeks. Even without definite radiographic findings, a child with localized tenderness consistent with a supracondylar fracture should be splinted and referred for follow-up examination within 24 to 48 hours. An x-ray performed a few weeks after the injury may reveal periosteal new bone formation in the supracondylar region. Patients with type I fractures can be discharged safely from the ED with instructions to elevate the extremity, apply ice, and have a follow-up evaluation in 1 to 2 days. Fractures that require manipulation usually warrant admission to the hospital to ensure compliance and for neurovascular monitoring. Minimally displaced (type II) fractures that are stable after reduction can be treated with splinting or casting with the elbow flexed. Some authors recommend flexion to 110 to 120 degrees for this injury. This position uses the intact posterior periosteum as a tension band to hold the reduction; however, if swelling or circulatory obstruction prevents this much flexion, it cannot and should not be used. The greater the flexion at the elbow, the greater is the chance of vascular impairment. When swelling peaks at 24 to 48 hours, the risk of vascular obstruction and compartment syndrome is the greatest. Occasionally, these injuries require percutaneous pinning to maintain stability, especially if a significant rotational component is present. Percutaneous pinning of fractures after reduction has grown in popularity in recent years and is recommended for type IIIB fractures with some studies showing better outcomes with pinning than without. Type III totally displaced fractures generally are the result of more severe injuries that produce more swelling than type I or type II injuries. Displacement necessitates the reestablishment of length, increases the chance of varus deformity and increases the chances of interposed soft tissues and neurovascular injury. For all these reasons, patients with type III fractures require emergency orthopedic consultation in the ED and should be admitted to the hospital for frequent neurovascular checks and closed reduction by an orthopedist and percutaneous pinning. Open reduction may be necessary if closed reduction is unsuccessful. Reduction in the ED is indicated only when the displaced fracture is associated with vascular compromise that threatens the viability of the extremity. Under these conditions, closed reduction should be attempted. After appropriate procedural sedation, an assistant fixes the arm of the patient. The physician grasps the patient’s wrist and applies steady, firm traction in line with the long axis of the limb (Fig. 45.15A). The forearm is kept in the neutral, thumb-up position. While traction is maintained, correction of any medial or lateral displacement is accomplished with the other hand at the elbow (see Fig. 45.15B). If the distal fragment is displaced laterally, it is pushed inward; if it is displaced medially, it is pushed outward. After length has been restored and the angular deformity has been corrected, the thumb of the free hand is placed over the anterior surface of the proximal fragment with the fingers behind the olecranon. While traction is maintained, the elbow is gently flexed to just beyond 90 degrees (see Fig. 45.15C). Angulation is corrected to a normal carrying angle. Only one attempt should be made at manipulation. Multiple attempts increase the likelihood of neurovascular injury and swelling. If reduction is unsuccessful, simple traction on the extended elbow may restore vascular supply. When reduction is performed, follow-up radiographs are obtained to ensure adequate reduction and neurovascular function is checked at frequent intervals. Cylinder casts are not applied initially because they increase the risk of forearm ischemia; a posterior plaster splint provides safe and adequate immobilization. Type IV injuries require emergent orthopedic consultation for complicated operative intervention. These injuries represent a surgical challenge, but recent studies show that a satisfactory outcome can be obtained.  

**Flexion Type Supracondylar Fractures**

**Clinical Features.** Flexion-type supracondylar injuries are much less common, with a reported frequency of about 2% of all supracondylar fractures. The mechanism of injury is a direct blow to the flexed elbow.

**Diagnostic Testing.** Plain films may reveal a simple increase in the anterior angulation of the distal supracondylar fragment or gross displacement of the distal fragment proximal and anterior to the distal end of the proximal fragment. In the latter case, the distal end of the proximal fragment protrudes posteriorly. A line drawn anterior humeral shaft (see earlier discussion in the Extension Type Supracondylar Fractures section) intersects the capitellum either normally or posteriorly in these fractures, depending on whether there is anterior displacement. The most common complication is nerve injury with injury to the ulnar nerve, occurring in over 90% of all nerve injuries. The radial and median nerves are rarely injured.

**Management and Disposition.** For flexion-type supracondylar injuries, when the posterior periosteum is torn, the anterior periosteum functions as a tension band with the arm in extension. In type I fracture, the periosteum is minimally displaced. These injuries do not need to be immobilized in extension. The elbow can be comfortably flexed and should be immobilized in a splint as with extension injuries. Type II and III injuries should be referred to an orthopedist immediately. Type II injuries are
Intercondylar Fractures

Clinical Features. These injuries are rare and generally are seen in adults in their 50s and 60s. The common mechanism of injury is direct trauma to the elbow that drives the olecranon against the humeral articular surface and splits the distal end. Patients with intercondylar fractures complain of pain at the elbow, which on examination is tender to palpation. Neurovascular complications are not common with these injuries.

Diagnostic Testing. Good-quality anteroposterior and lateral radiographic views are essential in evaluating fracture displacement and comminution (Fig. 45.18). Intercondylar fractures are usually T-shaped or Y-shaped fractures with variable degrees of separation of the condyles from each other and from the proximal humerus fragment (Fig. 45.19). The distal portion of the fracture extends to the articular surface of the distal humerus.

Transcondylar Fractures

Clinical Features. Both extension and flexion types of transcondylar fractures have been described based on the position of the elbow when fractured. Extension types are the most common with a mechanism of injury that is similar to that for supracondylar injuries. In contrast to supracondylar fractures, however, the injury is more common in elderly individuals with fragile, osteoporotic bone.

Diagnostic Testing. Transcondylar (or dicondylar) fractures have a fracture line, either transverse or crescent shaped, that passes through both condyles within the joint capsule just proximal to the articular surface (Fig. 45.17).

Management and Disposition. Transcondylar (or dicondylar) fractures are generally difficult to treat because the small distal fragment possesses little extra-articular bone, and only a small amount of bone contact is available for union. Orthopedic consultation in the ED should be obtained for these injuries. Both internal fixation and elbow arthroplasty are viable operative options, with internal fixation now supplanting primary elbow arthroplasty as the mainstay of treatment for most cases.
CHAPTER 45  Humerus and Elbow

Computed tomography may be used to delineate fracture patterns further.

Management and Disposition. Treatment of intercondylar fractures is difficult and complicated. The goal of treatment is to reestablish articular congruity and alignment and to begin active motion as soon as possible, most often through open reduction with rigid internal fixation. Closed treatment is typically restricted to elderly patients, patients with medical conditions that prohibit surgery, and certain patients with nondisplaced fractures, although recent literature shows that both closed and open methods may have similar results in children.16 These injuries all should be referred to an orthopedic surgeon immediately. As with supracondylar fractures, manipulation should be avoided unless limb-threatening ischemia is present. Traction across the elbow with the arm extended is helpful in restoring blood flow to an ischemic forearm.

Condylar Fractures

Clinical Features. Condylar fractures are rare in adults and typically involve the articular surface and the nonarticular portion of the distal humerus, including the epicondyle (Fig. 45.20). Lateral condylar fractures are uncommon, although more common than fractures of the medial condyle. The mechanism of injury is either a direct blow to the lateral aspect of the flexed elbow or a force that results in adduction and hyperextension with avulsion of the lateral condyle. Medial condylar fractures are rare and result from either a direct blow to the apex of the flexed elbow or a fall on the outstretched hand with the elbow forced into varus. The presentation of condylar fractures is similar to that of other distal humerus fractures, with swelling, tenderness, and crepitus localized over either the medial or the lateral elbow. On palpation, independent motion of the involved condyle may be appreciated. In lateral condylar fractures, findings may be accentuated with movement of the radius. In children, lateral condyle fractures are the second most common fractures involving the elbow, after supracondylar fractures.17 The fracture has an age distribution similar to that of supracondylar fracture and occurs after a fall on the outstretched hand, with a varus stress applied to the extended arm. Tenderness and swelling are noted over the lateral aspect of the elbow. In general, children exhibit less swelling than with supracondylar fractures and neurovascular compromise is uncommon. Because of the location of the ulnar nerve, it is imperative to test its function when this fracture is present. Medial condylar fractures are associated with tenderness over the medial condyle and pain with flexion of the wrist against resistance. Medial condyle fractures are rare in children, comprising 1% to 2% of pediatric elbow fractures.18 When they do occur, medial condylar fractures are considered type IV Salter-Harris injuries with physeal injury a possible outcome. The mechanism of injury is believed to be a valgus force on the extended elbow. The patient has tenderness and swelling over the medial aspect of the elbow.

Diagnostic Testing. Diagnosis is usually made on standard anteroposterior and lateral views, although an oblique view also may be helpful. These fractures are notoriously difficult to diagnose because fractures with minimal displacement are difficult to see radiographically and are often misdiagnosed as supracondylar humerus fractures. The status of the lateral trochlear ridge is the key to analyzing humeral condyle fractures. It may be involved with either medial or lateral condylar fractures and, when incorporated into the distal fragment, is far more likely to result in instability. On radiographic examination, lateral condylar...
fractures show a widening of the intercondylar distance. The distal fragment is often displaced, most commonly posteriorly and inferiorly. Displaced distal fragments tend to be anterior and inferior because of the pull of the forearm flexors. For medial condyle fractures, anteroposterior, lateral, and oblique films may show the fracture in older children, but because the trochlea does not ossify until about age 9, plain films in younger children do not show the fracture. Magnetic resonance imaging (MRI) may be necessary to confirm the diagnosis in these patients.

**Management and Disposition.** For condylar fractures, treatment depends on radiographic findings but much controversy exists about the accuracy of these findings and studies are being done to determine the best imaging method.18 For nondisplaced or minimally displaced condylar fractures, immobilization of the flexed elbow in a long arm posterior plaster splint is sufficient. Surgical intervention is recommended for a fragment incarcerated within the elbow joint, open fracture, nerve injury, or gross elbow instability.19 For fractures displaced more than 3 mm, surgical fixation is traditionally recommended, but there is some controversy around this with acceptable displacement ranging from more than 2 mm to 15 mm.19 Due to the high rate of complications, orthopedic consultation should be sought for all adult condylar fractures. For lateral condylar fractures, the forearm should be supinated and the wrist extended to relieve the tension on the extensor muscle attachments. For medial condylar fractures, the reverse is true (ie, the forearm should be pronated and the wrist flexed). Nondisplaced lateral condyle fractures are treated nonoperatively with a cast, whereas fractures with any displacement require closed or open reduction with percutaneous pin fixation for 3 to 4 weeks.17,37 For medial condylar fractures, operative treatment is indicated if displacement is greater than 2 mm; otherwise, conservative treatment is sufficient.

**Capitellum and Trochlea Fractures**

**Clinical Features.** Fractures of the capitellum and trochlea typically occur together, usually as a result of posterior dislocation of the elbow, with isolated fractures being less common. Injury to the capitellum occurs when the patient falls on an outstretched hand, forcing the radial head upward, similar to the motion of a pitcher’s windup. Isolated fractures are associated with focal tenderness on examination and flexion of the elbow increases pain because their attachment is along the medial epicondyle. Isolated fractures are associated with focal tenderness on examination and flexion of the elbow increases pain. Isolated fractures of the trochlea are exceedingly rare because of the structure’s protected position deep within the elbow joint. The shearing force of the ulna against the trochlea is transmitted primarily through the medial collateral ligament. Displaced distal fragments tend to be anterior and inferior because of the pull of the forearm flexors. For medial epicondyle fractures, a true lateral radiographic view of the elbow is recommended. A posterior fat pad or significant swelling of the joint should suggest concurrent injuries, such as elbow packs, elevation, compression, and analgesia. Accurate anatomic alignment, rigid internal fixation, and early mobilization are prerequisites for a good functional result.20 Fractures of the articular surfaces can be treated nonsurgically only if radiographs show perfect anatomic alignment. Nondisplaced trochlea fractures may be treated with a posterior splint for 3 weeks, followed by early range-of-motion exercises. Displaced fractures should be treated operatively; fragments that can be internally fixed are repaired, whereas small fragments are excised. Immobilization should be minimized to 10 to 14 days.39

**Epicondylar Fractures**

**Clinical Features.** Most epicondylar fractures involve the medial epicondyle. Medial epicondyle fractures are most common in children and adolescents and often involve the apophysis, which is the last ossification center to fuse in the distal humerus, usually after age 15. Fractures through this ossification center usually occur in adolescence and constitute 11% of pediatric elbow fractures. These are not Salter-Harris injuries, because the apophysis is involved rather than the physis. The lateral epicondyle is almost level with the flattened outer surface of the lateral condyle giving it only minimal exposure to a direct blow and fracture is extremely rare. Medial epicondyle injuries occur from a variety of mechanisms. First, avulsion fractures are associated with posterior elbow dislocations in patients younger than 20 years in up to 50% of cases.27 Avulsion fracture also may occur with severe or repeated stress, such as from arm wrestling or baseball pitching (Little Leaguer’s elbow). Finally, a direct blow to the medial epicondyle can cause this injury. The elbow is held in flexion and any movement is resisted. Isolated fractures are associated with focal tenderness over the medial epicondyle. Use of the forearm flexors increases pain because their attachment is along the medial epicondyle. Ulnar nerve function should be evaluated as associated ulnar nerve palsy may be present with an entrapped fragment.

**Diagnostic Testing.** Simple fractures of the medial epicondyle are extra-articular injuries with limited soft tissue injury.14 They generally do not produce a fat pad sign on the lateral radiographic view of the elbow. A posterior fat pad or significant swelling of the joint should suggest concurrent injuries, such as elbow...
CHAPTER 45  Humerus and Elbow

The neurovascular status should be examined with special attention given to the ulnar nerve distribution. Loss of sensation over the palmar aspect of the fifth digit and hypothenar eminence or motor weakness in the interossei muscles of the hand suggests ulnar nerve injury. Symptoms of ulnar nerve injury occur in 10% of patients and in most cases the injury is an ulnar contusion that resolves spontaneously.

Diagnostic Testing. Lateral radiographic views are most helpful. In addition to the fracture, the degree of comminution, the extent of articular surface disruption and the amount of displacement in the 90-degree flexion position should be noted.

Management and Disposition. In olecranon fractures, non-displacement in the 90-degree flexion position indicates that the triceps aponeurosis is intact and prolonged immobilization is unnecessary. Displacement of more than 2 mm is considered an indication for surgery (Fig. 45.23A). A fracture line that increases in separation with flexion of the elbow is also considered a displaced fracture. When this fracture is associated with elbow dislocation, the plane of instability is located through the fracture site and the radiohumeral joint resulting in posterior displacement of the proximal fragment of the ulna and anterior dislocation of the radius and ulna as a unit (see Fig. 45.23B). Nondisplaced fractures can be treated conservatively on an outpatient basis with triceps function. The neurovascular status should be examined with special attention given to the ulnar nerve distribution. Loss of sensation over the palmar aspect of the fifth digit and hypothenar eminence or motor weakness in the interossei muscles of the hand suggests ulnar nerve injury. Symptoms of ulnar nerve injury occur in 10% of patients and in most cases the injury is an ulnar contusion that resolves spontaneously.

Diagnostic Testing. Lateral radiographic views are most helpful. In addition to the fracture, the degree of comminution, the extent of articular surface disruption and the amount of displacement in the 90-degree flexion position should be noted.

Management and Disposition. For epicondylar fractures, if the fracture fragment is minimally displaced (<5 mm), treatment with a posterior splint is appropriate. To minimize distraction of the fragment by the forearm flexors, the elbow and wrist are flexed with the forearm pronated. Treatment of displaced fractures is controversial and often, the amount of displacement dictated the need for surgery, but results of operative and nonoperative treatment seem to be good regardless of the degree of displacement. Some experts advocate surgery for patients who participate in high-performance athletic activities that involve the injured extremity but controlled studies are lacking. Intra-articular fragments that cannot be removed from the joint by manipulation are an indication for surgery. Emergent orthopedic consultation should be sought for these injuries. The rare lateral epicondylar fracture in adults was previously treated with immobilization, but more recent experience indicates that operative management is more successful.

Olecranon

Clinical Features. Fractures of the olecranon may result most commonly from a direct blow as a result of a fall, a motor vehicle or motorcycle crash, or an assault. Less commonly, indirect force applied by forceful contraction of the triceps while the elbow is flexed during a fall can cause a transverse or oblique fracture through the olecranon. Olecranon fractures are uncommon in children. The anatomic integrity of the olecranon is essential for triceps strength and normal function of the elbow. Physical findings may include tenderness and pain over the olecranon, a palpable separation at the fracture site or the inability to extend the elbow against force. This last finding indicates complete discontinuity of the pulling mechanism and the consequent failure of triceps function. The neurovascular status should be examined with special attention given to the ulnar nerve distribution. Loss of sensation over the palmar aspect of the fifth digit and hypothenar eminence or motor weakness in the interossei muscles of the hand suggests ulnar nerve injury. Symptoms of ulnar nerve injury occur in 10% of patients and in most cases the injury is an ulnar contusion that resolves spontaneously.

Diagnostic Testing. Lateral radiographic views are most helpful. In addition to the fracture, the degree of comminution, the extent of articular surface disruption and the amount of displacement in the 90-degree flexion position should be noted.

Management and Disposition. For epicondylar fractures, if the fracture fragment is minimally displaced (<5 mm), treatment with a posterior splint is appropriate. To minimize distraction of the fragment by the forearm flexors, the elbow and wrist are flexed with the forearm pronated. Treatment of displaced fractures is controversial and often, the amount of displacement dictated the need for surgery, but results of operative and nonoperative treatment seem to be good regardless of the degree of displacement. Some experts advocate surgery for patients who participate in high-performance athletic activities that involve the injured extremity but controlled studies are lacking. Intra-articular fragments that cannot be removed from the joint by manipulation are an indication for surgery. Emergent orthopedic consultation should be sought for these injuries. The rare lateral epicondylar fracture in adults was previously treated with immobilization, but more recent experience indicates that operative management is more successful.

Olecranon

Clinical Features. Fractures of the olecranon may result most commonly from a direct blow as a result of a fall, a motor vehicle or motorcycle crash, or an assault. Less commonly, indirect force applied by forceful contraction of the triceps while the elbow is flexed during a fall can cause a transverse or oblique fracture through the olecranon. Olecranon fractures are uncommon in children. The anatomic integrity of the olecranon is essential for triceps strength and normal function of the elbow. Physical findings may include tenderness and pain over the olecranon, a palpable separation at the fracture site or the inability to extend the elbow against force. This last finding indicates complete discontinuity of the pulling mechanism and the consequent failure of triceps function. The neurovascular status should be examined with special attention given to the ulnar nerve distribution. Loss of sensation over the palmar aspect of the fifth digit and hypothenar eminence or motor weakness in the interossei muscles of the hand suggests ulnar nerve injury. Symptoms of ulnar nerve injury occur in 10% of patients and in most cases the injury is an ulnar contusion that resolves spontaneously.
Radial Head and Neck

Clinical Features. Radial head and neck fractures, in general, are produced by an indirect mechanism, typically a fall on an outstretched hand. The radius transmits the force upward, causing the radial head against the capitellum and resulting fracture of the weaker radial head or neck. Although the fracture of the radial head may be the only radiographic finding, damage to the articular surface of the capitellum and injury to the collateral ligament commonly occur. Displacement of the radial head fragment suggests considerable force and significant soft tissue injury. This injury is characterized by localized tenderness over the radial head or pain with passive rotation of the forearm.

Diagnostic Testing. Radiographic findings range from a subtle disruption of the usual gradual sweep of the radial neck and head surface to an obvious displaced or comminuted fracture (Fig. 45.24). Undisplaced fractures are notoriously difficult to see on radiographs. Tenderness coupled with a positive fat pad sign on the radiograph indicates that the injury should be treated as a radial head fracture even in the absence of a visible fracture. Radial head fractures are classified into four types: type I, undisplaced fractures; type II, marginal fractures (involving <30% of the articular surface) with more than 2 mm displacement, including impaction or angulation; type III, comminuted fractures of the entire radial head; and type IV, any of the previous types with elbow dislocation.

Management and Disposition. In radial head and neck fractures, type I nondisplaced fractures are treated symptomatically with a brief period of sling support and early range-of-motion exercises (within 24 to 48 hours). Aspiration of the hemarthrosis from the joint space may give dramatic relief of pain and improve the range of motion. Based on a prospective randomized study, which found no benefit to bupivacaine instillation compared with simple aspiration, we do not recommend injection of bupivacaine into the joint. Most patients with this injury recover well in 2 to 3 months. A few do poorly, however, with long-term pain, contracture, or inflammation. Type II injuries are usually treated similarly, with aspiration and immobilization in the ED, followed by a trial period of range-of-motion exercises. In these cases, aspiration of the joint not only relieves pain but also allows testing of the range of motion to identify entrapped fragments. Radial head excision is sometimes performed later if the patient fails to improve. Early excision is advised for type II fractures when a mechanical block is present and for most type III fractures. Long-term functional results after radial head excision are acceptable in most patients with relatively few having some functional disability after this procedure. Treatment of type IV injuries is directed at the elbow dislocation as described next and for the specific radial head lesion.

Dislocations/Subluxations

Elbow

Clinical Features. The elbow is inherently subject to mechanical instability because of its anatomic structure and dislocations are common. The elbow is second only to the shoulder as the most commonly dislocated large joint. Elbow dislocation is a term usually used to describe a disruption of the relationship between the humerus and the ulna. In general, the radius and ulna, bound together firmly by the annular ligament and interosseous membrane, displace as a unit. Most classifications refer to the abnormal position of the ulna relative to the humerus. The elbow most often dislocates posteriorly, although it may dislocate anteriorly, medially, or laterally (Fig. 45.25). Although rare, a divertgent dislocation, which is a dislocation between the radius and ulna concurrently with the ulnohumeral type, can occur. Dislocation of the elbow requires considerable energy and is often associated with fractures of adjacent bony structures and a fracture-dislocation injury is referred to as a complex elbow dislocation.

The mechanism of injury of a posterior elbow dislocation is a fall on the outstretched hand or wrist, the elbow being either extended or hyperextended at the time of impact. A valgus stress usually also occurs. Patients hold the elbow in flexion at approximately 45 degrees and have marked prominence of the olecranon. Some elbow dislocations may reduce spontaneously prior to presentation in the ED where significant swelling and tenderness may be the only findings. Because elbow dislocations are associated with brachial artery and median nerve injuries, careful neurovascular examination is important especially prior to any
Manipulation or reduction and should be repeated frequently. Radiographic evaluation is crucial before manipulation to rule out fractures that can mimic dislocation on examination. Several fractures, including fractures of the distal humerus, radial head, and coronoid process commonly occur in conjunction with dislocation, which need to be identified and treated when present. The most serious complication of elbow dislocation is vascular compromise. Severe disruption results in injury to the brachial artery in 5% to 13% of cases. Vascular injury should be considered when a wide opening between the tip of the olecranon and the distal humerus is palpated or seen on a radiograph. The presence of distal pulses is not proof of an intact artery; and if a question of vascular compromise exists, emergent vascular studies or consultation is indicated. Median nerve traction injuries and entrapment have been reported. Recurrent dislocation of the elbow is rare. Medial and lateral elbow dislocations are produced by a mechanism similar to that in posterior dislocations, with a vector of force displacing the ulna and radius as a unit either medially or laterally. Anterior dislocations are rare and occur as a result of a blow from behind to the olecranon while the elbow is in the flexed position. Severe associated soft tissue trauma is often present, including avulsion of the triceps mechanism or vascular disruption, and these dislocations are frequently open. On examination, the upper arm appears shortened, the forearm elongated and supinated, the elbow is fully extended and the olecranon fossa is palpable posteriorly.

**Diagnostic Testing.** A radiographic example of posterior elbow dislocation before reduction is provided in Figure 45.26. The anteroposterior view is the important to be able to visualize medial or lateral dislocations.

**Management and Disposition.** Rapid reduction of complete elbow dislocations is important to relieve pain and to prevent circulatory embarrassment or cartilaginous damage. Reduction should be attempted as soon as possible, especially if there is neurovascular compromise, and orthopedic consultation is usually not necessary to proceed. Intra-articular injection of local anesthetic may provide adequate analgesia to allow for closed reduction, but procedural sedation is very helpful and often required to facilitate reduction. Posterior dislocations are reduced with an assistant immobilizing the humerus and applying counter traction while traction is applied to the distal forearm. The ideal position is for the elbow to be flexed at 30 degrees with the forearm supinated while distal traction is applied. When the capitellum slides over the coronoid process, a coupling sound occurs as the articular surfaces mesh. If reduction is unsuccessful with this technique, the physician should apply downward pressure at the proximal forearm and apply pressure behind the olecranon while maintaining inline traction. This downward force may help “unlock” the coronoid process, which may be trapped in the olecranon fossa. The joint is gently moved through its normal range of motion to check stability. As with all reductions, neurovascular status should be checked before and after any reduction attempt. Post reduction radiographs are required to access concomitant fractures of the coronoid process or radial head or, in children, separation of the medial epicondylar apophysis. Post reduction management includes immobilization in a posterior splint with the elbow in as much flexion as circulation allows along with a sling. Circular casting should be avoided initially. Patients can be discharged with instructions to apply ice, elevate, and watch for signs of vascular impairment. If the elbow is stable after reduction, gentle range-of-motion exercises may be initiated in 3 to 5 days. Unstable joints may require either prolonged immobilization in the presence of ligamentous instability or internal fixation for instability associated with fracture. For medial and lateral elbow dislocations, reduction is carried out with the arm in slight extension but otherwise is similar to that for posterior dislocation. Care should be taken not to convert these to posterior dislocations during reduction. Complications and aftercare are the same as for posterior dislocations. Reduction of closed anterior dislocations is performed with distal traction of the wrist and a backward pressure on the forearm while the distal humerus is grasped. A click usually indicates that reduction has been achieved. These injuries have a higher incidence of vascular impairment than the more common posterior dislocation although ulnar nerve injuries are unusual. Emergent orthopedic referral is standard for open injuries or when vascular disruption is suspected.

**Radial Head Subluxation**

**Clinical Features.** Subluxation of the radial head (nursemaids’ elbow) is a common injury, representing more than 20%
of upper extremity injuries in children. Children 1 to 4 years old are most often affected, although cases have been reported in children 6 months to 15 years old. Girls are affected more commonly than boys, and the left arm is more commonly affected than the right.28 The classic history, which is present approximately half of the time, is that of the forearm being pulled while in pronation with the elbow extended with stretching of the annular ligament, allowing fibers to slip between the capitellum and the head of the radius, resulting in an inability of the child to supinate the arm.29 By the age of 5, the annular ligament becomes thick and strong and thus is far less likely to tear or be displaced. Other mechanisms include direct trauma to the elbow or a twisting motion of the arm. In children younger than 6 months old, the mechanism of subluxation involves rolling over in bed that may trap the involved forearm under the body with resulting longitudinal traction on the joint. Clinically, the arm is held in passive pronation, with slight flexion at the elbow. The child is unable or unwilling to move the arm. Resistance to supination and tenderness on direct palpation over the head of the radius are present. Swelling, ecchymosis and deformity are absent.

Diagnostic Testing. When the history is suggestive of radial head subluxation, radiographs are not necessary and are rarely useful. If there is swelling or deformity, if there is an uncharacteristic history, if the child does not resume use of the arm after reduction, or if there is a possibility of nonaccidental trauma, appropriate radiographic studies are recommended. If palpation of the forearm, wrist, or humerus away from the elbow elicits reproducible tenderness, radiographs should be taken to exclude other diagnoses.

Management and Disposition. Reduction may be attempted in children with typical presentations and is safe even when the classic history is absent. Although historically, supination-flexion has been the method most commonly used, hyperpronation has a significantly higher reported success rate of reduction on the first attempt and is the recommended method for reduction.30 With the hyperpronation method, the child’s elbow is supported with moderate pressure applied to the radial head. The examiner then grips the child’s distal forearm and hyperpronates the forearm, resulting in a click felt over the radial head (Fig. 45.27). In the supination-flexion method, reduction is achieved either by supination or pronation while applying direct pressure over the radial head. With the supination method, the forearm is supinated while slight pressure on the radial head is applied with the examiner’s thumb. In one continuous motion, the elbow is supinated and flexed with gentle axial pressure applied. A click often, but not always, is felt as the radial head reduces (Fig. 45.28). Many patients are asymptomatic within 5 to 10 minutes; 90% of patients regain use of the arm within 30 minutes. Because a fearful child often does not use even the successfully reduced limb, it is a good idea for the physician to leave the room and for parents to distract the child to show return of normal function. If function does not return within 24 hours, the patient should be reevaluated. After successful reduction, no additional treatment, immobilization, or activity reduction is necessary. Parents and caregivers should be instructed to avoid excessive traction on the child’s forearm to prevent recurrent radial head subluxation. The recurrent radial head subluxation rate is approximately 20%.31

Soft Tissue Disorders

Epicondylitis

Clinical Features. Epicondylitis (tennis elbow) is a term first introduced in the 1880s to describe an inflammatory process that involves the radiohumeral joint or lateral epicondyle of the humerus. It is a common exercise-related syndrome, and the mechanism is thought to be repetitive pronation and supination of the forearm. The actual pathologic nature of this syndrome is unclear. Radiohumeral bursitis or synovitis, tendinitis of the common extensor tendon, periostitis of the lateral epicondyle, and entrapment by scar tissue of the radial nerve all have been suggested as causes of this syndrome. Histologically, the abnormality has been described as angiofibroblastic hyperplasia, a term subsequently modified to angiofibroblastic tendinosis. It is thought to be a degenerative process because of the paucity of acute inflammatory cells seen histologically.32 Most cases are lateral, but medial tennis elbow and posterior tennis elbow have been reported, the former involving the pronator teres and flexor carpi radialis insertions and the latter involving the triceps tendon. Onset is usually gradual and patients report dull pain over the lateral aspect of the elbow over the lateral epicondyle or radiohumeral joint, increased by grasping or twisting motions. Supination and pronation against resistance may be painful, and pain can be elicited by stretching the wrist extensors. To test this, the elbow is extended, the forearm pronated and the wrist fully dorsiflexed.

![Fig. 45.27. Hyperpronation method of radial head subluxation reduction. A, Support elbow with pressure to radial head. B, Then hyperpronate the arm distally.](image-url)
Fig. 45.28. Subluxation of the radial head. Method of reduction: Apply pressure to radial head (A), supinate the forearm (B), and flex elbow (C), in one continuous motion.

Diagnostic Testing. Radiographic findings may be normal, although with chronicity, calcifications may be present over the lateral epicondyle. Characteristic MRI findings also have been described, although MRI is not indicated emergently.

Management and Disposition. Traditional treatment includes protection, rest, ice, compression, elevation, and medication. Initial therapy includes avoidance of the inciting activity and immobilization with a sling. Nonsteroidal antinflammatory drugs (NSAIDs) are often used, but their efficacy probably is limited to their analgesic rather than their antinflammatory properties. Injection of a corticosteroid at the point of tenderness provides some pain relief in most patients.32,48 Because corticosteroids weaken collagen, injection directly into the tendon and premature resumption of heavy loading of the tendon at the lesion should be avoided. Patients with pain that persists despite treatment and a rehabilitation program should be referred for possible surgery.25 Modification of athletic technique is recommended after the symptoms subside.

Olecranon Bursitis

Clinical Features. Olecranon bursitis is commonly caused by repetitive minor trauma, such as leaning on the elbow during work activities. It also may result from an inflammatory process, such as gout or an infectious process within the bursa (septic bursitis). Septic olecranon bursitis occurs most commonly in patients engaged in work that predisposes to repetitive trauma to the elbow, such as gardening or plumbing. Although several bursae are located in the elbow region, the olecranon bursa is the one most often involved in an isolated pathologic process. Patients usually have progressive pain, tenderness and swelling over the olecranon. Some patients with septic bursitis have an abrupt onset instead, with a rapid increase in pain over a few hours and on examination, the septic bursa is typically swollen, hot, erythematous, and tender. Flexion is limited by pain brought on by tightening of the skin over the inflamed bursa. Minor breaks in the skin, frank abrasions, or healing lacerations over the bursa may be present. Noninfectious bursitis usually manifests with less warmth and erythema. The skin is intact and swelling may be the only finding.

Diagnostic Testing. The most important aspect of evaluation is the differentiation of a septic process from a benign inflammatory one, and this differentiation may be difficult on clinical grounds because considerable overlap exists in the histories and physical findings. If doubt exists, aspiration of the bursa should be performed and the aspirate sent for crystals, white blood cell (WBC) count, Gram’s stain, and cultures. Unless the aspirate is frankly bloody, traumatic nonseptic olecranon bursitis usually has a leukocyte count lower than 1000 cells/mm³, whereas septic bursal fluid usually has a count higher than 10,000 WBCs/mm³.

Management and Disposition. Aspiration is diagnostic and therapeutic because relief of pressure relieves some of the pain. In cases of purulent bursitis, the bursa should be drained and appropriate antibiotics should be prescribed. Pending culture results, empirical antibiotics should include coverage for routine skin organisms, as well as methicillin-resistant Staphylococcus aureus (MRSA). Sulfamethoxazole/trimethoprim double-strength twice daily or doxycycline 100 mg should be used twice daily for 10–14 days. For patients with severe inflammation or who are immunocompromised, intravenous vancomycin 15 to 20 mg/kg per dose every 8 to 12 hours should be used. Bursitis refractory to aspiration and appropriate antibiotics may require incision and drainage. Noninfectious bursitis can be managed with a compression dressing, ice, NSAIDs, and avoidance of the inciting activity. Patients who have had their bursa aspirated should be rechecked within 24 to 48 hours to verify culture results and monitor their response to treatment.

Biceps Tendon Rupture

Clinical Features. Biceps tendon rupture occurs most commonly in the proximal portion of the long head of the biceps. It is most common in middle-aged athletes or physical laborers who sustain repetitive microtrauma to the tendon. Patients experience a snapping sound and pain in the anterior shoulder during strenuous activities that produce rapid loading of the muscle. Rupture also occurs distally, usually as an avulsion from the insertion on the radial tuberosity, although ruptures at the musculotendinous junction occasionally occur. Rupture of the distal biceps tendon occurs almost exclusively in men, most commonly between the ages of 40 and 60, and most often involves the dominant arm.33,24 The inciting event is usually an unexpected extension force applied to the arm flexed at 90 degrees. The pathophysiology of tendon rupture is poorly understood, although tendon rupture generally occurs in the setting of underlying tendinosis. Diabetes, chronic renal failure, systemic lupus erythematosus, rheumatoid arthritis, and steroid or fluoroquinolone therapy all may result in tendinosis. Smoking has been shown to be strongly associated with distal...
biceps tendon rupture. In proximal tendon rupture, the patient usually has a visible defect at the top of the bicipital groove with bunching of the muscle distally. Flexing of the elbow produces pain at the proximal insertion but flexion remains intact, because the short head of the biceps usually maintains its integrity. With distal ruptures, the patient reports pain and tearing in the antecubital region. Visible deformity and a palpable defect of the biceps muscle belly are present with weakness of elbow flexion and supination. If the tendon is completely ruptured, there is a bunching up of the muscle and this effect is accentuated when the patient attempts flexion.

**Diagnostic Testing.** Radiographs are not revealing and usually not necessary. MRI may be useful when a partial rupture is suggested but can be obtained in follow-up and is not indicated in the ED.

**Management and Disposition.** All patients require referral to an orthopedist within 72 hours for evaluation for early anatomic repair of complete ruptures. Partial ruptures occasionally respond to conservative treatment but often require surgical repair. The arm is splinted and the patient advised to apply ice and be given analgesics while awaiting orthopedic consultation.

---

**KEY CONCEPTS**

- Clinical decision rules for the elbow joint have not been validated. Radiographs should be obtained when there is limitation in range of motion, moderate to severe pain, obvious deformity, joint effusion, or significant tenderness or crepitus over any of the bony prominences or the radial head. The threshold for imaging should be lower in pediatric patients (with the exception of presentation consistent with radial head subluxation) owing to the presence of open growth plates and limitations to the physical examination.
- In children with wrist pain and traumatic mechanism of injury, the absence of a clear-cut explanation for the pain (eg, no abnormal radiographic findings) should prompt consideration of an elbow injury causing referred pain to the wrist.
- On lateral elbow x-ray, a small anterior fat pad, parallel to the anterior surface of the humerus, can be a normal finding. Any convex ("sail sign") anterior fat pad and all posterior fat pads are pathological and indicate presence of joint effusion. In the setting of trauma, almost all patients with the posterior fat pad sign of the elbow have intra-articular skeletal injury. In adults, a posterior fat pad sign is indicative of a radial head fracture, whereas in children, a supracondylar fracture is the probable underlying injury. In the absence of trauma, inflammation and infection also cause effusion with positive fat pad signs.
- Radial nerve injury is the most common complication of humeral fracture and occurs 20% of the time. This is most often a benign neurapraxia that resolves spontaneously, although recovery may take several months. Radial nerve injuries associated with penetrating trauma or open fractures are likely to represent anatomical disruption and usually warrant operative exploration.
- Generally the radius and ulna, bound together firmly by the annular ligament and interosseous membrane, displace as a unit and typically dislocate posteriorly.
- Biceps tendon rupture occurs almost exclusively in men, most commonly between ages 40 to 60, usually subsequent to an unexpected extension force applied to the arm flexed at 90 degrees. Smoking, diabetes, chronic renal failure, systemic lupus erythematosus, rheumatoid arthritis, and steroid or fluoroquinolone therapy may predispose to this injury.

CHAPTER 45: QUESTIONS & ANSWERS

45.1. A 23-year-old man presents with arm pain and weakness after a gunshot wound to the left upper arm. Physical examination is remarkable for a small penetrating wound at the midlateral aspect of the biceps muscle, extensor weakness of the thumb and wrist, and intact distal pulses. Which of the following statements is true?
A. Angiography is indicated.
B. Cervical radiography is warranted.
C. Operative exploration is indicated.
D. The neurapraxia should resolve.
E. Urgent nerve conduction studies are indicated.

Answer: C. Radial nerve palsy resulting from penetrating injury or open fractures is often permanent and warrants operative exploration. Nerve conduction studies would not be abnormal until approximately 3 weeks post injury.

45.2. A 4-year-old boy is brought to the emergency department (ED) by his mother after falling from a swing set. He complains of right wrist pain and resists detailed examination of the arm. Radiographs are normal. What is the most appropriate next step in this patient’s management?
A. Computed tomography (CT) scan of the wrist
B. Elbow radiograph
C. Reassurance
D. Splinting for 3 to 6 weeks
E. Triple-phase bone scan after 7 to 10 days

Answer: B. In children with wrist pain and traumatic mechanism of injury, the absence of a clear-cut explanation for the pain (e.g., normal radiograph) should prompt suspicion for an elbow injury producing referred pain.
Shoulder

Rachel R. Bengtzen | Mohamud R. Daya

**CHAPTER 46**

**PRINCIPLES**

The shoulder joint is a unique and complex articulation unit. It has the largest range of motion of any appendicular joint in the body and can be moved through a space that exceeds a hemisphere in extent.

Shoulder injuries are commonly encountered in emergency medicine and dislocations account for more than 50% of all major joint dislocations seen in the emergency department (ED). The shoulder can be injured by trauma (indirect or direct) or by overuse.1

In general, children are vulnerable to the same injuries as those incurred by adults; however, the presence of the epiphysial and its growth plate changes the pattern of injuries.2 The strength of the joint capsule and its ligaments is two to five times greater than that of the epiphysial plate. An injury that produces a sprain or dislocation in an adult often causes a fracture through the hypertrophic zone of the growth plate in a child. Most shoulder injuries in children can be treated conservatively, with a good prognosis for full return of function.2

**Anatomy**

The shoulder girdle connects the upper extremity to the axial skeleton (Fig. 46.1). The sternoclavicular joint (SCJ) represents the only true articulation between the upper extremity and the axial skeleton. The SCJ participates in all movements of the upper extremity and is the most moved joint in the body (Fig. 46.2). The superior mediastinum with its great vessels, trachea, esophagus, thoracic duct, lung apices, and other important structures is immediately posterior to the SCJ.

The clavicle is an S-shaped bone that acts as a strut to support the upper extremity and keep it away from the chest wall, also protecting the subclavian vessels and brachial plexus. The middle third, which is thin and untethered, is the most commonly fractured segment.3

The acromioclavicular joint (ACJ) connects the lateral end of the clavicle with the medial aspect of the acromion process (Fig. 46.3). The ACJ has little or no bony stability and is dependent on the associated ligaments and muscles for support.4

The scapula is a flat triangular bone that forms the posterior aspect of the shoulder girdle. The thin body of the scapula lies flat against the posterior thorax and widens laterally to form the glenoid fossa. The scapula’s thickened borders are the attachment sites for 18 muscle origins and insertions.5 The thick muscle coat and ability to recoil along the posterior chest wall protect the scapula from both direct and indirect trauma.

The glenohumeral articulation is a ball-and-socket–type joint that depends largely on associated capsule, muscles, and ligaments for stability (Fig. 46.4).6 The absence of bony stability permits a range of motion greater than any other joint.

The proximal humerus articulates with the glenoid fossa and provides for the attachment of many important muscles. The rotator cuff stabilizes the glenohumeral joint (GHJ) and consists of the supraspinatus, infraspinatus, teres minor, and subscapularis muscles (Fig. 46.5). The long head of the biceps tendon originates from the supraglenoid tubercle and ascends over the humeral head to enter the arm via the bicipital groove (see Fig. 46.5). Long muscles that cross the articulation are involved primarily in movements of the GHJ. The pectoralis major, latissimus dorsi, and teres major muscles all insert into the humeral intertubercular groove. Displacements encountered with fractures of the humerus usually reflect the pull of these attached muscle groups. The proximal humerus is composed primarily of trabecular bone with a thin cortical shell. Changes in bone density with age increase the risk of fractures.7

The brachial plexus and subclavian vessels enter the shoulder girdle superiorly between the clavicle and the first rib, traverse under the coracoid process, and exit anterior to the inferior aspect of the GHJ as the median, ulnar, and radial nerves and axillary vessels. These nerves represent the final branches of the upper brachial plexus (nerve roots C5 to C8).

**CLINICAL FEATURES**

**History**

Most complaints involve some combination of pain, stiffness, instability, or weakness. Pain can result from many different conditions extrinsic and intrinsic to the shoulder. Extrinsic sources of shoulder pain include disorders of the cervical spine, thoracic outlet myocardium, as well as symptoms referred from processes causing diaphragmatic irritation.

For intrinsic conditions, the most important factors to determine are the time and mechanism of injury (traumatic or overuse), the precise location of the pain, and associated sensorimotor complaints. Shoulder pain also can manifest in an insidious manner, unrelated to any precipitating factor. In these instances, the duration, location, character, and aggravating and alleviating factors of the pain should be noted.

Stiffness usually manifests as a restricted range of motion resulting from an underlying painful condition of the shoulder. Instability can be chronic or acute and seen in the form of an obvious subluxation or dislocation or a sensation of the shoulder almost “going out.” A rotator cuff tear or an underlying nerve lesion usually causes significant shoulder weakness.

**Physical Examination**

The shoulder should be inspected from the anterior, posterior, and lateral positions in addition to the axilla. Any obvious deformity, ecchymosis, laceration, swelling, or hematoma should be noted.

Palpation of the shoulder should be performed systematically, beginning at the SCJ and moving laterally to the ACJ. Next, the scapula, GHJ, and humerus are palpated. Any point tenderness, crepitus, swelling, or deformity should be noted.

Active and passive ranges of motion should be tested although this may be limited due to acute pain. Active range of motion is best determined with the patient in the sitting position to

Fig. 46.1. Anatomy of the shoulder girdle. It consists of three bones: the clavicle, humerus, and scapula; three joints: the acromioclavicular, glenohumeral, and sternoclavicular joints; and one pseudoarticulation: the scapulothoracic pseudoarticulation. (From Roy S, Irwin R: Sports medicine: prevention, evaluation, management and rehabilitation, Englewood Cliffs, NJ, 1983, Prentice Hall.)

Fig. 46.2. The sternoclavicular joint (SCJ) is stabilized by several ligaments. (Redrawn from DePalma AF: Surgery of the shoulder, ed 3, Philadelphia, 1983, JB Lippincott.)

Fig. 46.3. Ligaments of the acromioclavicular joint (ACJ). (Redrawn from DePalma AF: Surgery of the shoulder, ed 3, Philadelphia, 1983, JB Lippincott.)

Fig. 46.4. Anatomy of the glenohumeral joint (GHI). A synovial membrane extends from the glenoid fossa to the humeral head. Overlying the synovial membrane is a loose and redundant fibrous capsule. Anteriorly, the capsule is thickened to form the superior, middle, and inferior glenohumeral ligaments. The anterior band of the inferior glenohumeral ligament is the most important restraint to anterior glenohumeral dislocations.
CHAPTER 46  Shoulder

Shoulder checked, although collateral circulation may preserve this despite an underlying vascular injury. The presence of pallor, paresthesias, or a significant hematoma should raise concern for a vascular injury. The neurovascular examination should be repeated after any manipulation in the ED.

DIAGNOSTIC TESTING

Radiology

The initial assessment of traumatic injuries includes a three-view trauma series of radiographs consisting of true anteroposterior (45-degree lateral), transscapular lateral (“Y” view), and axillary lateral views. The true anteroposterior view is preferred over standard anteroposterior views, because it shows the GHJ without any bony overlap. Standard anteroposterior views obtained with the joint in internal and external rotation profile the lesser and greater tuberosity and are more useful in the evaluation of soft tissue conditions.

Orthogonal views include the axillary lateral, transscapular lateral, and apical oblique. The preferred view is the axillary lateral, which projects the GHJ in a cephalocaudal plane helping to define the position of the humeral head with the glenoid fossa and identify lesions of the coracoid process, humeral head, and glenoid rim. The difficulty in obtaining this view is commonly due to pain has led to the popularity of the transscapular view. Advantages of this projection include its simplicity, reproducibility, and clear delineation of anatomic structures. In this view, the scapula is projected as a Y, with the body forming the lower limb and the coracoid and acromion processes forming the upper limbs. The humeral head normally is superimposed over the glenoid, which is located at the junction of the three limbs. This view is particularly useful in identifying anterior and posterior glenohumeral dislocations. The apical oblique view (obtained by having the patient stand bending forward, and angling the central ray 45 degrees caudally) shows the GHJ in a unique coronal

eliminate the contributions of the lumbar spine and lower extremity joints. Passive range of motion is best evaluated in the supine position. The degrees of abduction, forward flexion, extension, and internal and external rotation should be compared with those for the unaffected extremity. In addition, observe the motion of the scapulothoracic articulation. After 45 degrees of abduction, the scapula moves approximately 1 degree for every 2 degrees of glenohumeral motion. Specific strength tests for the rotator cuff include resisted internal rotation (subscapularis), resisted external rotation (infraspinatus and teres minor), and the empty can test (supraspinatus). The empty can test is performed with the patient resisting downward pressure with their arm raised forward to 90 degrees, with arm extended and pronated, such that the thumb is down (as if pouring out a can of liquid).

The examination is completed with an assessment of the neurovascular function. A complete sensory (light touch and pinprick) and full motor examination of the brachial plexus should be performed (Table 46.1). The radial pulse should be checked, although collateral circulation may preserve this despite an underlying vascular injury. The presence of pallor, paresthesias, or a significant hematoma should raise concern for a vascular injury. The neurovascular examination should be repeated after any manipulation in the ED.

DIAGNOSTIC TESTING

Radiology

The initial assessment of traumatic injuries includes a three-view trauma series of radiographs consisting of true anteroposterior (45-degree lateral), transscapular lateral (“Y” view), and axillary lateral views. The true anteroposterior view is preferred over standard anteroposterior views, because it shows the GHJ without any bony overlap. Standard anteroposterior views obtained with the joint in internal and external rotation profile the lesser and greater tuberosity and are more useful in the evaluation of soft tissue conditions.

Orthogonal views include the axillary lateral, transscapular lateral, and apical oblique. The difficulty in obtaining this view is commonly due to pain has led to the popularity of the transscapular view. Advantages of this projection include its simplicity, reproducibility, and clear delineation of anatomic structures. In this view, the scapula is projected as a Y, with the body forming the lower limb and the coracoid and acromion processes forming the upper limbs. The humeral head normally is superimposed over the glenoid, which is located at the junction of the three limbs. This view is particularly useful in identifying anterior and posterior glenohumeral dislocations. The apical oblique view (obtained by having the patient stand bending forward, and angling the central ray 45 degrees caudally) shows the GHJ in a unique coronal
Clinical Features. The patient has pain over the fracture site, and the affected extremity is held close to the body. This positioning is a result of the effect of gravity and the pull of the muscles (pectoralis major, latissimus dorsi, sternocleidomastoid) on either side of the fracture site. The head is often tilted toward the injured side in an attempt to relax the effects of these displacing muscular forces. Ecchymosis, crepitus, and a palpable or visible deformity may be noted over the fracture site. Examine for any tenting of the skin, because this can cause progression to an open fracture. Although rarely present, it is prudent to evaluate for associated neurovascular and pulmonary injury due to close proximity of the subclavian vessels, brachial plexus, and apex of the lung.11

Diagnostic Testing. Clavicle-specific plain radiographs may be required to confirm the presence of a fracture, although most clinically significant fractures are diagnosed on chest or shoulder radiographs. Fractures in children can be reliably diagnosed or ruled out by bedside ultrasound, decreasing the exposure to radiation (Fig. 46.8).9

Management. Principles of initial management for simple fractures include pain control, some form of immobilization primarily for comfort, and proper follow-up care. In addition to oral analgesics, pain associated with clavicle fractures can also be managed with an ultrasound-guided superficial cervical plexus block in the ED.12 Fractures of the clavicle are adequately immobilized with a simple sling. Figure-of-eight bandages are no longer recommended.13 Emergent orthopedic consultation should be sought for open fractures or fractures associated with neurovascular injuries, skin tenting, or interposition of soft tissues. More urgent orthopedic consultation (before 72 hours) is recommended for type II lateral clavicle fractures, because these fractures have up to a 30% incidence of nonunion and may require surgical repair.1 Severely comminuted or displaced fractures of the middle third (defined as over 18 mm of initial shortening) are associated with a higher incidence of nonunion and long-term functional deficits and so should be referred for early orthopedic evaluation for consideration of operative reduction.14 Additional risk factors associated with nonunion in midclavicular fractures include smoking, female sex, and advancing age.15

**SPecific Injuries**

**Fractures**

**Clavicle**

**Principles.** The clavicle accounts for 3% to 5% of all fractures with a 2:1 male to female ratio and is the most commonly fractured bone in children. Clavicular fractures are classified anatomically and mechanistically into three groups. Fractures of the medial third are uncommon (5%) and occur as a result of a direct blow to the anterior chest. Fractures of the middle third are the most frequent (Fig. 46.6), accounting for 80% of all injuries. The usual mechanism of injury involves a direct force applied to the lateral aspect of the shoulder as a result of a fall, sporting injury, or motor vehicle collision (MVC). Fractures of the lateral third (15%) result from a direct blow to the top of the shoulder and are classified further into three subtypes.1 Type I fractures are stable and minimally displaced because the coracoclavicular ligament remains intact. Type II fractures are associated with a torn coracoclavicular ligament and have a tendency to displace because the proximal fragment lacks any stabilizing forces (Fig. 46.7). Type III injuries involve the articular surface.
Disposition. Most fractures of the clavicle heal uneventfully, and follow-up can be provided by a primary care physician. A sling should be worn until the patient is comfortable, which may precede radiographic evidence of callous formation. Early passive shoulder range-of-motion exercises (Figs. 46.9 and 46.10) are encouraged to reduce the risk of adhesive capsulitis (so-called “frozen shoulder”). Adolescents and adults generally require 4 to 8 weeks of immobilization. Contact sports should be avoided until the bone healing is solid (6 to 8 weeks). Full range of motion of the shoulder and an absence of pain are two reliable clinical signs that the fracture has healed.

Complications. The most common complications are delayed union, nonunion, and symptomatic malunion.1 Displaced middle third fractures have a 15% to 20% rate of nonunion and up to 25% rate of symptomatic malunion.14 Vascular complications after fractures of the medial third resemble those associated with posterior sternoclavicular dislocations. Type III lateral clavicle fractures can lead to subsequent ACJ osteoarthritis.

Scapula

Principles. Fractures of the scapula are rare accounting for approximately 1% of all shoulder fractures and are caused by high-energy trauma, such as high-speed MVCs and falls from significant height.16 Scapular fractures rarely require management but are associated with major injury (75% to 98%) specifically, injuries to the ipsilateral lung, chest wall, and shoulder girdle complex.5 The most common associated orthopedic injuries are fractures of the ribs, proximal humerus, and clavicle. Associated lung injuries, including pneumothorax, hemothorax, and pulmonary contusion, usually occur acutely but may manifest up to 2 to 3 days after the initial injury. Associated injuries of the head, spinal cord, brachial plexus, and subclavian or axillary vessels are less common.5

The Orthopaedic Trauma Association classification system is based on the severity and prognosis associated with these fractures. Fractures are divided into two main types: extra-articular (neck [Fig. 46.11], body, acromion process, coracoid process, spine) and intra-articular (with partial or total glenoid involvement).17

Clinical Features. In a conscious patient, the shoulder is held in a position of most comfort; adducted with the arm held close to the body, and any attempts at movement will result in significant pain. Tenderness, crepitus, or hematoma may be noted over the fracture site. The clinical findings occasionally mimic those with a rotator cuff tear.
**Diagnostic Testing**

**Radiology.** The three-view trauma shoulder series will reveal most scapular fractures, as will careful examination of the scapula on the trauma chest radiograph. An os acromiale (unfused acromial process epiphysis) is present in 3% of the population, will not be tender to examination, and should not be confused with a fracture of the acromion. A comparison film can be useful, because the abnormality is present bilaterally in 60% of cases. Although additional dedicated scapula views can be obtained in the ED, the presence and the extent of scapular injury is best determined by CT. In the event that a trauma chest CT scan has been obtained to search for associated injuries, a three-dimensional reconstruction of the scapula should be requested to define the nature and extent of the injury.

**Management.** Presence of a scapular fracture should prompt a thorough search for associated thoracic, intracranial, orthopedic, and neurovascular injuries. Most fractures, including fractures with severe comminution heal rapidly with nonoperative therapy. Initial therapy consists of analgesia, immobilization in a sling for comfort to support the ipsilateral upper extremity, and passive range-of-motion exercises (see Fig. 46.10). Most patients require a sling for 2 to 4 weeks, physical therapy, and follow-up assessment for delayed displacement. Fractures of the proximal humerus separate along old epiphyseal lines, producing four distinct segments consisting of the articular surface (anatomic neck), greater tuberosity, lesser tuberosity, and humeral shaft (surgical neck). Neer’s classification system is based on the relationship of these fracture fragments. In this system, a segment is considered displaced if it is angled more than 45 degrees or separated more than 1 cm from the neighboring segment. Because this classification system considers only displacement, the number of fracture lines is irrelevant. There are four major categories of fracture: (1) minimal displacement (Fig. 46.12), (2) two-part displacement (Fig. 46.13), (3) three-part displacement, and (4) four-part displacement. When present, anterior and posterior dislocations are included as part of the classification. Impaction and head-splitting fractures are classified separately.

The classic mechanism of injury involves a fall on an outstretched abducted arm. Concurrent pronation limits further abduction and lever the humerus against the acromial process; this produces a fracture or dislocation, depending on the tensile strengths of the bone and surrounding ligaments. Older patients are prone to fracture, whereas younger persons are apt to have dislocations. The combined injury (fracture and dislocation) may be seen in middle-aged patients. Proximal humerus fractures also may result from a direct blow to the lateral side of the arm or from fractures that extend into the suprascapular notch. Delayed complications include adhesive capsulitis and rotator cuff dysfunction.

**Proximal Humerus**

**Principles.** Fractures of the proximal humerus occur primarily in the older population, in whom structural changes (osteoporosis) weaken the proximal humerus, predisposing it to injury from low-energy falls. Although most of these injuries involve minimal displacement and are adequately managed with conservative therapy, significantly displaced fractures may require operative intervention. Displacements encountered with fractures of the humerus usually reflect the pull of the attached muscle group.

Fractures of the proximal humerus separate along old epiphyseal lines, producing four distinct segments consisting of the articular surface (anatomic neck), greater tuberosity, lesser tuberosity, and humeral shaft (surgical neck). Neer’s classification system is based on the relationship of these fracture fragments. In this system, a segment is considered displaced if it is angled more than 45 degrees or separated more than 1 cm from the neighboring segment. Because this classification system considers only displacement, the number of fracture lines is irrelevant. There are four major categories of fracture: (1) minimal displacement (Fig. 46.12), (2) two-part displacement (Fig. 46.13), (3) three-part displacement, and (4) four-part displacement. When present, anterior and posterior dislocations are included as part of the classification. Impaction and head-splitting fractures are classified separately.

The classic mechanism of injury involves a fall on an outstretched abducted arm. Concurrent pronation limits further abduction and lever the humerus against the acromial process; this produces a fracture or dislocation, depending on the tensile strengths of the bone and surrounding ligaments. Older patients are prone to fracture, whereas younger persons are apt to have dislocations. The combined injury (fracture and dislocation) may be seen in middle-aged patients. Proximal humerus fractures also may result from a direct blow to the lateral side of the arm or from fractures that extend into the suprascapular notch. Delayed complications include adhesive capsulitis and rotator cuff dysfunction.
support operative treatment of four-part fractures in the elderly; the procedure of choice is hemiarthroplasty.\(^7,15,19\)

Fracture-dislocation injuries are best managed in consultation with an orthopedic surgeon before attempts at reduction (except in cases of neurovascular compromise or unavailability of an orthopedic surgeon). Of note, reductions of these injuries in the ED may be unsuccessful, and manipulation can cause separation of previously non-displaced segments. Closed reduction under fluoroscopic control and general anesthesia is preferable.

**Complications.** The most common complication of proximal humeral fractures is adhesive capsulitis. This complication can be prevented by the early initiation of pendular shoulder exercises, along with a thorough rehabilitation program. One of the most devastating complications is avascular necrosis (AVN), which is more common in multi-part fractures, and fracture-dislocations due to the disruption of the blood supply to the humeral head.\(^5\) Repeated forceful attempts at reduction of fracture-dislocations may be associated with subsequent heterotopic bone formation (myositis ossificans). Neurovascular injuries (axillary nerve, brachial plexus, and axillary artery) may be encountered with displaced surgical neck fractures and fracture dislocations.

**Proximal Humeral Epiphysis**

**Principles.** Fractures of the proximal humeral epiphysis are uncommon and account for a small proportion of pediatric fractures.\(^20\) The injury can occur at any age while the epiphysis remains open but is most common in adolescent boys. The most common mechanism of injury involves a fall onto the outstretched hand, and the fracture typically occurs through the zone of hypertrophy in the epiphysial plate. Injuries can be classified according to their location (Salter system), stability, and degree of displacement.\(^20\)

**Clinical Features.** The patient holds the injured arm tightly against the body, using the opposite hand. The area over the proximal humerus is swollen and tender to palpation. Radiographs obtained at 90 degrees to each other confirm the diagnosis. Comparison views may be helpful with minimally displaced fractures. Point of care ultrasound has also been demonstrated to accurately identify these injuries, with a sensitivity of approximately 90%.\(^7\)

**Management.** Fractures of the proximal humeral epiphysis can result in significant permanent injury and disability as the physis accounts for 80% of the longitudinal growth of the bone. Urgent orthopedic consultation should be obtained for all such injuries.

**Complications.** Complications are rare and include mal-union, growth plate disturbances, and injuries to the neurovascular bundle. Markedly displaced or angulated fractures are more likely to result in a residual loss of mobility.

**Dislocations**

**Sternoclavicular**

**Principles.** SCJ dislocations are infrequent and account for less than 1% of all dislocations.\(^21\) Significant forces are required to disrupt the strong ligamentous stabilizers of this joint. The most common causes are MVCs and injuries sustained in high impact contact sports. The vast majority of dislocations are anterior. Posterior dislocations, although less common, can be associated with life-threatening injuries within the superior
elbow and supported across the trunk by the opposite arm and pain results from any movement of the upper extremity or lateral compression of the shoulders. The SCJ may be mildly swollen and tender to palpation. With an anterior dislocation, the displaced medial end of the clavicle may be palpable. Posterior dislocations are associated with more severe pain, are caused by higher intensity direct force and may be associated with and may accompany complaints of hoarseness, dysphagia, dyspnea, and weakness or paresthesias in the ipsilateral upper extremity. The patient’s neck is often flexed toward the injured side at rest and the clavicular notch of the sternum may be palpable along. Hoarseness may be related to tracheal injury. Damage to the innominate vein may present as cyanosis and venous congestion of the neck and should prompt vascular imaging and consultation.21,23

Diagnostic Testing. Although diagnosed clinically, sternoclavicular dislocation requires radiological confirmation. Findings on standard anteroposterior, oblique, and specialized (40-degree cephalic tilt) SCJ views are difficult to interpret. These dislocations and associated injuries are best visualized by CT (Fig. 46.16). Ultrasound imaging may be a useful adjunct.24

Management. Treatment of grade I injuries includes sling immobilization for comfort and primary care follow-up. Immobilization generally is maintained until symptoms improve and full painless motion is restored. Grade II injuries should be immobilized with a sling and the patient referred for orthopedic follow-up care. Grade II injuries require a longer course of immobilization (4 to 6 weeks) and are more likely to be associated with persistent pain.21 Grade III injuries should be managed by closed reduction and rarely open reduction.

Anterior dislocations may be reduced in the ED with proper analgesia and on occasion may require general anesthesia (Fig. 46.17). Stable reductions should be maintained in a sling and referred for orthopedic follow-up care.21 Most reductions are unstable; and because the deformity is primarily cosmetic and not functional, the treatment of choice for recurrent anterior dislocations is benign neglect.

Posterior dislocations constitute true orthopedic emergencies and should be reduced expeditiously.21 Ideally, reduction of posterior dislocations should be attempted under general anesthesia, although when not feasible or in the setting of airway or vascular compromise can be attempted in the ED with use of procedural sedation. Emergency reduction may be required for patients with
Reduction of dislocated sternoclavicular joints (SCJs). A rolled sheet is placed posteriorly between the shoulder blades to elevate both shoulders approximately 5 cm above the table. Traction is applied to the arm in an extended (10- to 15-degree) and abducted (90-degree) position. If reduction does not occur, an assistant can add inward pressure on the medial end of the clavicle. (From Simon RR: Emergency orthopedics: the extremities, ed 7, Norwalk, CT, 2015, McGraw-Hill.)

Complications. Complications of anterior injuries are primarily cosmetic. By contrast, 30% of posterior dislocations may be complicated by life-threatening injuries to intrathoracic and superior mediastinal structures.21 These include compression or laceration of the great vessels, tracheoesophageal fistula, tracheal compression, pneumothorax, thoracic outlet syndrome, and brachial plexus injuries. These injuries are best visualized though a chest CT angiogram.

Acromioclavicular Joint

Principles. Injuries of the ACJ occur primarily in young men as a result of MVC, bicycle accidents, or participation in high impact contact sports. The most common mechanism of injury involves a fall or direct blow to the point of the shoulder with the arm adducted. The weak acromioclavicular ligaments rupture first. With increasing force, the coracoclavicular ligament ruptures, and the attachments of the deltoid and trapezius muscles are torn from the distal clavicle. The ACJ also can be injured after a fall onto the outstretched hand.

Classification is based on the degree of damage sustained by the acromioclavicular and coracoclavicular ligaments (Fig. 46.18) and classified according to the Rockwood 6-class grading system.26

Clinical Features. Patients should be examined while they are upright, because the supine position can mask ACJ instability, and it is helpful to visualize both shoulders simultaneously to assess for symmetry. Type I and type II injuries are associated with
mild tenderness and swelling over the ACJ margin, with minimal deformity and full range of motion (although painful). Patients with type III, IV, V, and VI injuries are characterized by severe pain and patients hold the arm tightly abducted to reduce traction stress across the joint. In type III injuries, the shoulder hangs downward and the clavicle rides high, producing a characteristic clinical deformity that can be reduced by an upward force under the elbow. In type IV injuries, the clavicle may be palpable posteriorly, and in type V injuries, the clavicle may be palpable subcutaneously above the acromion, and unlike type III is not reducible by elbow pressure. In type VI injuries, the shoulder assumes a flattened clinical appearance as seen from the side.

**Diagnostic Testing**

**Radiology.** The recommended projections include routine anteroposterior and an axillary lateral view to evaluate for vertical migration of the clavicle and anteroposterior displacement, respectively. A Zanca view (an anteroposterior with 15-degree cephalic tilt view) can improve visualization by removing the scapula from behind the joint. Anteroposterior and Zanca views are ideally obtained with a view of both joints on a single-wide film. Standing radiographs can help unmask a higher-grade injury. The normal coracoclavicular distance ranges from 11 to 13 mm. A difference of more than 5 mm between the injured and uninjured sides is diagnostic of a complete coracoclavicular disruption. With type I injuries, the radiographic appearance is essentially normal. With type II injuries, radiographs show upward or posterior displacement of the clavicle so that the lower margin of the clavicle is clearly cephalad to the lower margin of the acromion, and normal coracoclavicular distance is preserved. With type III, IV, and V injuries, radiographic features include a widened joint, an increased coracoclavicular distance, and either superior or posterior displacement of the clavicle (Fig. 46.19) with the lower margin of the clavicle cephalad to the upper margin of the acromion. Stress views of the ACJ are no longer recommended, because they are uncomfortable for patients and are not clinically necessary.

**Management.** Type I and II injuries should be immobilized in a sling for comfort and to remove stress on injured ligaments. Patients with these injuries can be referred for follow-up with their primary care physician. When pain has subsided (1 to 2 weeks), gradual range-of-motion and strengthening exercises can begin, with a return to sports when pain-free function has been achieved (usually 2 to 6 weeks). The management of type III injuries is variable, although most favor initial nonoperative management. Selected patients who are young, are serious athletes, have severe displacement (more than 2 cm), and perform repetitive overhead activities may be candidates for surgical intervention. Treatment of type III injuries in the ED should consist of sling immobilization and sports medicine or orthopedic referral. Type IV, V, and VI injuries require early surgical treatment.

**Complications.** The most common concurrent injuries are associated fractures of the clavicle and coracoid process. The most common complications of ACJ injuries are residual symptomatic instability and joint tenderness due to secondary degenerative changes.

**Glenohumeral Dislocations**

**Principles.** The GHJ is the most commonly dislocated major joint in the body. There are two distinct age peaks, the first in men 20 to 30 years old and the second in women in their 60s. The GHJ can dislocate anteriorly, posteriorly, inferiorly, or superiorly. Anterior dislocations account for 96% to 98% of all glenohumeral dislocations. Posterior dislocations account for most of the remainder, whereas inferior (luxatio erecta) and superior dislocations are rare.

**Anterior Dislocations**

**Pathophysiology.** Anterior dislocations can result from indirect or direct forces. In younger persons, the injury usually is sustained during athletic activities involving rapid movements with the arm elevated, abducted and externally rotated, or rarely by a direct force applied posterolaterally. A characteristic pathologic feature is avulsion of the anteroinferior glenohumeral ligament with capsulolabral detachment (Bankart’s lesion). In older patients, a fall onto the palm of an outstretched arm is the more common mechanism of injury.

Anterior dislocations can be classified according to their cause (traumatic or nontraumatic), frequency (primary or recurrent), and the anatomic position of the dislocated humeral head (Figs. 46.20 and 46.21). In most dislocations (99%) the humeral head will assume a subcoracoid or subglenoid position. Of these, the subcoracoid is more common, and the head is displaced anteriorly and rests inferior to the coracoid process. Subclavicular and intrathoracic dislocations are extremely rare and involve the addition of strong lateral to medial forces that push the humeral head medially.

**Fig. 46.19.** Third-degree sprain of the left acromioclavicular joint (ACJ). The coracoclavicular distance is increased. Bilateral clavicle view (patient is standing) can assist in comparison to the unaffected side. (Courtesy Erik Foss, MD.)

**Fig. 46.20.** Types of anterior dislocation. A, Subcoracoid. B, Subglenoid. C, Subclavicular. D, Intrathoracic. (From DePalma AF: Surgery of the shoulder, ed 3, Philadelphia, 1983, JB Lippincott.)
Clinical Features. The patient presents in severe pain often supporting the dislocated shoulder with the opposite extremity. The lateral edge of the acromion process is prominent, and the normally rounded shoulder assumes a “squared-off” appearance. The coracoid process is indistinct, and the anterior shoulder appears full. The patient leans away from the injured side and cannot adduct the shoulder even slightly without severe pain. Dislocations can be associated with injuries of the brachial plexus, axillary nerve or artery. Almost half of patients will have some degree of nerve injury, although most of these are clinically inconsequential and are more frequent in patients older than 50 years old.27,28

Diagnostic Testing

Radiology. Radiographs will confirm the clinical diagnosis and identify the position of the humeral head, although they are not required before relocation in otherwise healthy patients with a recurrent dislocation and without significant concomitant injury or diagnostic uncertainty. Point of care ultrasound may be useful as a diagnostic adjunct.8 Some patients with a dislocation will have an associated fracture—most commonly, a compression fracture of the posterolateral aspect of the humeral head (Hill-Sachs deformity) caused by forceful impingement against the anterior rim of the glenoid fossa. Hill-Sachs fractures are not clinically significant unless they are large enough to cause recurrent shoulder instability or painful clicking or catching, in which case surgical repair may be necessary.

Management. Reduction of the dislocation should be accomplished expeditiously, because the incidence of neurovascular complications increases with time as does the difficulty with which the fracture can be reduced due to muscle spasm. For most patients, reduction may be attempted before imaging after a discussion with the patient. A postreduction film remains advisable to aid in the identification of glenoid rim fractures, as well as Hill-Sachs deformities, which when large can be associated with subsequent shoulder instability.

Bedside ultrasound can also be used to diagnose dislocations and assess for successful relocation after reduction attempts. In a study that added ultrasound to usual ED care, the assessment diagnosed 100% of dislocations and had a sensitivity of 100% for assessing complete reduction. Clinicians can consider using it to confirm reduction prior to obtaining postreduction radiographs.

Procedural sedation is often used to facilitate reduction in the ED. Adequate analgesia often can also be provided through intra-articular injection of a local anesthetic agent. This technique is especially useful when procedural sedation is contraindicated. Longer acting local anesthetic agents (such as, bupivacaine) may also offer continued postreduction analgesia. Multiple studies have found intra-articular lidocaine achieved a similar reduction effectiveness (RR 0.92) when compared with procedural sedation with fewer complications.27 Depending on the duration of the dislocation, nature (primary vs. recurrent) and technique, reduction can also be attempted and accomplished successfully without the use of any analgesia or sedation, provided the examiner is prepared to abandon the procedure if the patient experiences pain.30

Reduction can be accomplished with various techniques, most of which involve traction, leverage, or scapular manipulation principles.1 The ideal method should be simple, quick, and effective; require little assistance; and cause no additional injury to the shoulder. It is important to be familiar with several techniques of reduction because none are uniformly successful. Several common techniques are described in Table 46.2. Clues to a successful reduction include feeling of a “clunk,” relief of pain, normalization of anatomy, and improvement in range of motion. The neurovascular examination should be repeated and recorded after any reduction attempt. Most of these techniques are usually effective; however, approximately 5% to 10% of dislocations cannot be reduced in the ED and require reduction under anesthesia.1 After reduction, the affected extremity is immobilized with a sling and swathe bandage for comfort. Patients should be discharged with adequate analgesia and follow-up. Primary dislocations and complicated cases (associated fracture, rotator cuff tear, axillary nerve injury) should follow up with an orthopedist. Immobilization duration can be individualized depending on age, if a first time or recurrent dislocator, or if there are associated Bankart’s fractures. General recommendation from the ED is sling immobilization for 1 to 2 weeks until orthopedic follow-up.1 The most important postreduction therapy is a rehabilitation program aimed at restoring the static and dynamic stabilizers of the GHJ, which follows the period of immobilization.6

Complications. Complications include fractures and neurovascular injuries. Most axillary nerve injuries are neurapraxic, management is expectant, and the prognosis for recovery of function is good.27 Rotator cuff tears are especially common in primary dislocations in patients older than 40 years old, increasing to 80% in patients over 60 years old.27,30 In this setting, failure to abduct the arm is commonly confused with an axillary nerve injury. Most of these patients require tendon and capsular repair to restore shoulder stability. Recurrence also is a common complication after anterior dislocation, and patients younger than 30 years old have recurrence rates of 79% to 100%. A Hill-Sachs deformity, Bankart’s lesion, or a glenoid rim fracture are associated with increased risk of recurrence.6 The traditional method of treatment (immobilization followed by physical therapy) is ineffective in preventing redislocation in young athletic patients. Arthroscopic studies of primary anterior dislocations in such patients have detected a high incidence of anterior-inferior capsulolabral avulsions (Bankart’s lesion) from the glenoid rim. This avulsion is believed to be the primary predisposing factor for recurrence, and affected patients seem to benefit from early arthroscopic repair of the lesion.30 Recurrence rates decline with increasing age and in the presence of a greater tuberosity fracture.27,31

**Techniques to Reduce Anterior Shoulder Dislocations**

<table>
<thead>
<tr>
<th>REDUCTION TECHNIQUE</th>
<th>DESCRIPTION</th>
</tr>
</thead>
</table>
| **Stimson (hanging weight)**
  
  Patient placed prone with the dislocated shoulder hanging over the edge of the examining table. Attach a 10- or 15-pound weight to the wrist or lower forearm provides traction in forward flexion. Reduction usually occurs over 20 to 30 minutes (Fig. 46.22). | |
| **Traction/countertraction**
  
  Apply traction along the abducted arm while an assistant uses a folded sheet wrapped across the chest applies countertraction. Although commonly used it requires more force than other techniques (Fig. 46.23). | |
| **External rotation method**
  
  No traction involved. Patient seated or in supine, the involved arm is slowly and gently adducted to the side. The elbow is flexed to 90 degrees, and slow, gentle external rotation is applied to achieve reduction (Fig. 46.24). Success rates with this method range from 80% to 97%. | |
| **Cunningham**
  
  Patient sits without slouching in a hard backed chair. Adduct the affected arm to the body and place elbow in full flexion resting against operator’s shoulder. Operator then provides traction by placing their wrist on patient’s forearm while asking the patient to shrug shoulders superiorly and posteriorly. The operator adds massage down through the trapezius, deltoid, and the biceps muscles. This technique is targeted to relax muscles causing a dynamic obstruction. | |
| **Milch technique**
  
  Patient is placed supine and the head of the bed is elevated 20 to 30 degrees. The affected arm is held by the wrist and slowly abducted and externally rotated. The operator stops whenever resistance to motion is encountered and continues when the patient is relaxed. If the humerus has not reduced by the time 90 degrees of abduction and 90 degrees of external rotation have been reached, gentle longitudinal traction is applied along the humerus while the free hand is used to exert lateral and superior pressure on the humeral head to complete the maneuver. The effectiveness of this method has been attributed in part to more conical symmetry of the muscle forces acting across the glenohumeral joint (GHJ). | |
| **FARES**
  
  A variation of the Milch technique called FARES (FAst, RELiable, and Safe). FARES adds oscillation in a vertical direction while the affected arm is abducted. It is more effective, faster, and less painful than the traction/countertraction and Kocher methods. | |
| **Scapular manipulation**
  
  Reduction is accomplished by repositioning the glenoid fossa rather than the humeral head. Manipulation can be combined with the other techniques, particularly Stimson or traction/countertraction.

  Apply traction (manual or hanging weights), and then manipulate the scapula by rotating the inferior tip medially and stabilizing the superior and medial edges with the opposite hand. This technique can also be used in a seated position in which a second operator applies traction in the forward horizontal position. Scapular manipulation can be difficult in obese patients, in whom it is difficult to palpate and grasp the inferior tip of the scapula (Fig. 46.25). | |
| **Not recommended**
  
  Hippocratic method (traction with the foot in the axilla) and the Kocher maneuver (leverage, adduction, and internal rotation), are no longer recommended because of a high incidence of associated complications (axillary nerve injury, humeral shaft and neck fractures, capsular damage). | |

---

*May also be attempted with minimal to no analgesia or sedation.

---

**Fig. 46.22.** Stimson or hanging weight method of reduction for anterior shoulder dislocations.

**Fig. 46.23.** Traction/countertraction method for reducing anterior shoulder dislocations.
while performing an abduction and external rotation maneuver. The patient also may relate a sensation of the shoulder’s slipping in and out. The radiographic appearance usually is normal, and presence of an apprehension sign confirms the diagnosis. For this sign to be elicited, the injury motion (abduction and external rotation of the arm) is gently reproduced while an anterior force is applied to the posterior shoulder. This maneuver increases the pain and may cause anterior displacement of the humeral head. With a positive test result, the patient will actively resist further external rotation and appear apprehensive. A lax or redundant anterior capsule is thought to be responsible for this syndrome, and recurrent episodes are common. These patients can be placed in a sling for comfort with instructions on pendulum exercises, and they should be referred for orthopedic follow-up care because definitive therapy (capsulorrhaphy) is surgical.

**Posterior Dislocation**

**Pathophysiology.** Posterior dislocations are uncommon, accounting for fewer than 5% of all glenohumeral dislocations. The glenoid fossa acts as a partial buttress protecting against posterior dislocations. Posterior dislocations are easily missed on initial evaluation unless x-rays are obtained in two planes and carefully reviewed and, if missed, may remain unrecognized (“locked posterior dislocations”) for weeks or months. A posterior dislocation can result from several distinct mechanisms of injury. A posterior dislocation can occur after a fall onto the outstretched hand with the arm held in flexion, adduction, and internal rotation or after a direct blow to the anterior aspect of the shoulder. Convulsive seizures (epileptic or after electrical shock) have been associated with unilateral or bilateral posterior dislocations. A seizure disorder should be suspected in cases of unexplained nocturnal posterior dislocations. Acute posterior dislocations are anatomically classified into three types—subacromial (most common), subglenoid, and subspinous—based on the final resting position of the humeral head.

**Clinical Features.** Early diagnosis is essential to prevent long-term complications. Obtaining true orthogonal images (axillary or scapular view) can prevent misdiagnosis. The affected arm is held across the chest in adduction and internal rotation. The normal shoulder contour is replaced by a flat, squared-off appearance, and the coracoid process is prominent and easily palpated. The humeral head may be palpable posteriorly beneath the acromion process. Abduction is severely limited, external rotation is completely blocked, and restricted forearm supination may be present.

**Diagnostic Testing**

**Radiology.** True or standard anteroposterior radiographs can appear deceptively normal with posterior dislocations. Radiographic features include loss of the half-moon elliptic overlap of the humeral head and glenoid fossa on a standard anteroposterior film. In addition, the distance between the anterior glenoid rim and the articular surface of the humeral head is increased (the rim sign). The humeral head is profiled in internal rotation and takes on a “lightbulb” or “drumstick” appearance (Fig. 46.26A). A true anteroposterior film shows abnormal overlap of the glenoid fossa with the humeral head (see Fig. 46.26B) and can be useful in visualizing an impaction fracture of the anteromedial humeral head (reverse Hill-Sachs deformity). This fracture may produce a curvilinear density on the frontal projection parallel to the articular cortex of the humeral head (the trough sign). An orthogonal view, such as a transscapular Y (see Fig. 46.26C), axillary lateral (see Fig. 46.26D), or apical oblique view, confirms the diagnosis. The axillary lateral view or apical oblique view also identifies associated fractures of the humeral head and posterior glenoid.

**Anterior Subluxation**

Transient anterior subluxation of the shoulder is encountered often in young athletic adults. The patient reports sudden sharp shoulder pain and weakness (“dead arm syndrome”) that occurred...
Complications. Posterior glenohumeral dislocations usually are associated with anteromedial impression fractures of the articular surface. A similar fracture of the posterolateral aspect of the humeral head is present with anterior dislocations (Hill-Sachs deformity). Impression fractures involving more than 20% of the articular surface usually are unstable and require surgical repair post reduction.

Fractures of the glenoid rim, greater tuberosity, lesser tuberosity, and humeral head account for most associated injuries. The subscapularis muscle rarely may be avulsed from its insertion site on the lesser tuberosity. Neurovascular injuries are uncommon because the anterior location of the neurovascular bundle protects it from injury.

Inferior Glenohumeral Dislocation (Luxatio Erecta)

Pathophysiology. Luxatio erecta is a rare type (<0.5%) of glenohumeral dislocation in which the superior aspect of the rim. If an adequate orthogonal view cannot be obtained, shoulder CT should be considered. Bedside ultrasound has also been used to diagnose posterior shoulder dislocations in the ED.

Management. Closed reduction may be attempted in the ED with procedural sedation. The technique incorporates internal rotation and lateral traction to disimpact the humeral head from the glenoid rim. In the absence of humeral neck fracture or significantly engaged reverse Hill-Sachs lesion, the Stimson technique can also be used (see Table 46.2). If unsuccessful, reduction with the patient under general anesthesia is indicated. After reduction the shoulder should be immobilized in a sling, or if available in an external rotation sling with slight abduction (can use towel roll) until orthopedic follow-up in 1 to 2 weeks. Cases that were missed initially and manifest as chronic or “locked” posterior dislocations should be discussed with the orthopedist, because they often require semielective open reduction and internal fixation or arthroplasty.

Fig. 46.26. Routine anteroposterior (A) radiograph of a posterior dislocation. Note the “lightbulb” or “drumstick” appearance of the humeral head while in internal rotation. True anteroposterior (B), transscapular (C), and axillary (D) radiographic views of a posterior glenohumeral dislocation. Note the abnormal overlap of the glenoid rim and humeral head.
 humeral head is forced below the inferior rim of the glenoid fossa (Fig. 46.27). Application of a direct axial load to an abducted shoulder also can disrupt the weak inferior glenohumeral ligament and drive the humeral head downward.

Clinical Features. Clinically, the patient has the arm locked overhead in 110 to 160 degrees of abduction. The elbow usually is flexed, and the forearm typically rests on top of the head. The shoulder is fixed in this position. The inferiorly displaced humeral head may be palpable along the lateral chest wall. A thorough neurovascular examination is essential to evaluate for associated injuries.

Diagnostic Testing
Radiology. Luxatio erecta are easily mistaken and diagnosed and treated as subglenoid anterior dislocations, because the radiographic features are remarkably similar. Standard anteroposterior radiographs show the superior articular surface inferior to the glenoid fossa (Fig. 46.28). In addition, the humeral shaft characteristically lies parallel to the spine of the scapula on the anteroposterior view. This radiographic feature is useful in distinguishing luxatio erecta from a subglenoid anterior dislocation; in the latter, the humeral shaft lies parallel to the chest wall. Associated fractures of the acromion, coracoid, clavicle, greater tuberosity, humeral head, and glenoid rim are common.

Management. Reduction usually can be accomplished by traction/countertraction maneuvers (Fig. 46.29) under procedural sedation. Regional anesthesia in the form of an ultrasound guided interscalene block has also been reported to be an effective for facilitating reduction. Multiple attempts may be necessary; occasionally, “buttonholing” of the capsule will prevent closed reduction, necessitating an orthopedic consultation for open reduction. An alternative approach is the two-step closed reduction maneuver in which the inferior dislocation is first converted into an anterior dislocation before being reduced. The two-step maneuver requires a single operator, fewer attempts, minimal force, and only local analgesia or minimal procedural sedation.

Complications. Neurapraxic lesions of the brachial plexus are common, and thrombosis of the axillary artery has also been associated with luxatio erecta. Other associated injuries include tears of the rotator cuff, damage to the glenoid labrum, and avulsion fractures of the greater tuberosity.

Scapulothoracic Dissociation
Scapulothoracic dissociation is a rare and severe injury characterized by complete disruption of the scapulothoracic articulation and may be thought of as a partial or complete closed internal forequarter amputation of the upper extremity. Mechanism of injury involves a high energy force directed over the shoulder with severe traction applied to the ipsilateral upper extremity. Approximately half of the reported cases involve motorcycle accidents, with the injury occurring when the motorcyclist hangs onto the handlebars while the body is forced away. Because most patients present with significant concomitant trauma, the
Impingement Syndromes

Principles. The differential diagnosis of impingement syndrome is extensive and includes intrinsic and extrinsic causes of shoulder pain. Extrinsic sources include the cervical spine, lung, heart, and diaphragm. Intrinsic conditions include acromioclavicular arthritis, adhesive capsulitis, calcific tendinitis, traumatic anterior subluxation, as well as a pathophysiologic continuum from rotator cuff tendinitis or tendinopathy and subacromial bursitis to the endpoint of rotator cuff rupture.

The subacromial space is the area between the coracoacromial arch and the greater tuberosity of the humerus. This space, which is only a few millimeters wide, contains the long head of the biceps, the rotator cuff, and the subacromial bursa. The bursa provides the gliding mechanism between the musculotendinous cuff and the coracoacromial arch. Impingement can occur during shoulder forward flexion, between 60 to 120 degrees of abduction and in the extremes of adduction. The critical wear from impingement is centered on the supraspinatus tendon, near its insertion on the greater tuberosity. Narrowing of the subacromial space (anatomic variants of anterior acromion) and occupations that require excessive overhead activity accelerate the entire process resulting in rotator cuff tendinitis. With time, the inflammatory reaction spreads to involve the adjacent bursa. This inflammation leads to edema, thickening, and fibrosis, further narrowing the subacromial space (secondary impingement) eventually followed by attritional changes within the rotator cuff. Because the rotator cuff is a primary humeral head depressor, loss of function adds to the secondary impingement process.

The impingement process also may involve the long head of the biceps. In such cases, bicipital tendinitis, degeneration, or rupture may be present. If osteoarthritis of the ACJ has narrowed the subacromial space, the pathologic process can be accelerated. Impingement in this context occurs at 120 to 180 degrees of abduction (Fig. 46.31).

Clinical Features. The spectrum of illness is marked by a progression of symptoms. Initially patients report a dull ache around the deltoid area after strenuous activity. The inflammatory...
process within the bursa and tendons then leads to the formation of minor adhesions. Disruption of these adhesions is thought to account for the pain becoming more persistent and particularly severe at night. Significant tendon degeneration after a prolonged history of tendinitis and bursitis, can lead to tears in the rotator cuff.

On examination, tenderness can be elicited over the supraspinatus and anterior acromion. A painful arc of abduction at 60 to 120 degrees (see Fig. 46.31) has a sensitivity and specificity of 53% and 76%, respectively. The Hawkins-Kennedy impingement sign (arm placed into 90 degrees of flexion followed by internal rotation), has a sensitivity and specificity of 79% and 59%, respectively.42

**Management.** Initial treatment in impingement syndrome is conservative and consists of rest, simple analgesia using acetaminophen or analgesic doses of nonsteroidal antiinflammatory drugs (NSAIDs), and modification of activities that produce impingement. Patients should be advised to seek primary care follow-up if not better within 1 to 2 weeks for consideration of physical therapy to maintain range of motion and strengthen the rotator cuff. Treatment-refractory disease may eventually require decompression surgery to control pain.

**Rotator Cuff Tears**

**Principles.** The rotator cuff acts as a dynamic stabilizer of the GHJ. Its primary function is to hold the humeral head in place throughout the full range of rotational motion (see Fig. 46.5). The infraspinatus and teres minor act as external rotators, whereas the subscapularis is an internal rotator. The supraspinatus is essential for the first 30 degrees of shoulder abduction.

The tenuous blood supply of the rotator cuff, abusive tensile overload, and chronic wear under the coracoacromial arch predispose it to age-related degenerative changes and impingement. The advanced stage of this process is characterized by complete rupture.

Rotator cuff tears typically involve the dominant arm and occur in men older than 40 years old. The occupational history is significant for strenuous work requiring overhead activity. Tears can be classified according to their chronicity, size, completeness, pattern location, or duration. Acute tears (10%) usually are associated with a specific traumatic event. Often, no history of previous shoulder problems can be identified. The most common mechanism of injury is forced abduction associated with significant resistance; this usually occurs when the patient attempts to break a fall with an outstretched hand.

**Clinical Features.** With acute tears, patients report a sudden tearing sensation in the shoulder followed by severe pain that radiates into the arm. Pain and muscle spasm limit shoulder motion. Physical findings depend on the completeness, size, and location of the tear. Point tenderness is usually present over the site of rupture (greater tuberosity). Patients with large tears cannot initiate shoulder abduction. A discrepancy between active and passive range of motion is highly suggestive of a rotator cuff tear. The drop-arm test, performed by passively abducting the arm to 90 degrees and asking the patient to hold the arm in this position, is positive with significant tears. Slight pressure on the distal forearm or wrist causes the patient to drop the arm suddenly. The acute pain resulting from hemorrhage and spasm subsides over a few days. Repeat examination at this point confirms the loss of function in significant tears.

Chronic tears account for approximately 90% of all lesions. Chronic tears are attritional and more insidious in their presentation. Early findings include the painful arc sign as a result of secondary impingement. The pain is worse at night and interferes with sleep. Worsening pain is followed by the gradual onset of weakness in the arm. Flexion and abduction are affected with involvement of the supraspinatus. The patient attempts to initiate abduction with scapulothoracic movement. A tear in the subscapularis tendon weakens internal rotation. A tear in the teres minor or infraspinatus compromises external rotation.

**Diagnostic Testing**

**Radiology.** Plain radiographs likely will be normal in acute and chronic tears and are not generally indicated. If they are obtained, there may be evidence of nonspecific degenerative changes within the GHJ and subacromial space. The hallmark of a complete tear is superior displacement of the humeral head best seen on an external rotation view. The normal distance from the superior aspect of the humerus to the undersurface of the acromion ranges from 7 to 14 mm. A distance of less than 6 mm is highly suggestive of a complete tear. Outpatient ultrasound examination, MRI, or an MRI arthrogram can confirm the diagnosis. Point-of-care ultrasound appears to be an excellent initial screening test for the detection of partial- and full-thickness rotator cuff tears (Fig. 46.32). When compared to MRI, ultrasound evaluation had a sensitivity of 91% and a specificity of 86%.41

**Management.** Acute tears should be immobilized in a sling for comfort and the patient referred for orthopedic follow-up. Early surgical repair (before 3 weeks) for certain lesions is preferred in young or active individuals. The management of chronic tears includes pain control and a shoulder rehabilitation program. Orthopedic follow-up care may be needed as patients with persistent pain and weakness may require surgical repair.

**Lesions of the Biceps Muscle**

The biceps is composed of two heads. The long head originates from the supraglenoid tubercle and glenoid labrum and ascends over the humeral head to enter the arm by way of the bicipital groove. The long head is covered by a synovial sheath and is held in place within the groove by the coracoacromial and transverse humeral ligaments. The short head of the biceps originates from the coracoid process and inserts with the long head onto the radial tuberosity. The biceps is responsible for flexion as well as supination at the elbow and serves as a stabilizer for the GHJ.

**Bicipital Tendinitis**

**Pathophysiology.** Anatomically, the long head of the biceps is subject to the same stresses as those incurred by the rotator cuff within the subacromial space. Irritation and microtrauma as a
result of repetitive elevation or abduction of the shoulder produce an inflammatory reaction within the synovial sheath. Bicipital tendinitis is often associated with other acromial arch impingement conditions. Primary bicipital tendinitis (inflammation without other underlying pathology) is rare (approximately 5% of cases) and affects younger individuals.

The typical patient is middle-aged and involved in an occupation or recreational activity that requires repetitive overhead movement. The pain localizes to the anterior part of the shoulder along the bicipital groove. There is usually no history of trauma. Abduction and external rotation in particular are painful. Pain is worse at night and may interfere with sleep.

Clinical Features. On examination, point tenderness can be elicited over the biceps tendon as it passes through the bicipital groove. This is best shown with the arm in 10 degrees of internal rotation. Active range of motion is limited by pain, but the passive range remains intact. Supination against resistance—the Yergason test—with the arm adducted and the elbow flexed to 90 degrees reproduces the pain in 50% of cases. Another provocative test is the biceps resistance test (Speed test), in which forward flexion of the shoulder (elbow extended and forearm supinated) carried out against resistance produces pain in the bicipital groove. The specificity of these tests is limited in the presence of impingement and rotator cuff disease.

Diagnostic Testing

Radiology. Radiographs are usually normal and not indicated unless fracture or dislocation is suspected. When obtained, they may show evidence of subacromial space impingement by associated acromioclavicular arthritis and osteophytic spurs. The preferred imaging modality is ultrasound or MRI. Ultrasound has been found to be excellent in diagnosing complete rupture, subluxation or dislocation, but is less sensitive for partial tears.

Management. Emergency treatment consists of rest (sling for comfort), ice, and acetaminophen or analgesics doses of an NSAID. Gentle exercises are encouraged as symptoms subside. Although the bicipital sheath can be injected by landmarks with a corticosteroid preparation, the procedure is technically difficult, and inadvertent direct tendon injection can lead to tendon rupture. We do not recommend injection treatment of bicipital tendinitis in the ED. Surgery may be necessary in patients who fail to respond to conservative therapy.

Ruptures of the Biceps Tendon

Principles. Ruptures of the biceps tendon can be classified into proximal and distal types. Distal ruptures are rare and are not discussed here. Proximally, microtears and other age-related attritional changes within the long head predispose it to rupture. The rupture can be spontaneous or follow a traumatic event involving either forced extension or resisted supination and flexion.

Clinical Features. The classic history of an acute rupture is that of a sudden snap or pop, followed by pain and ecchymosis along the arm. Recent fluoroquinolone and oral steroid use may show evidence of subacromial space impingement by associated acromioclavicular arthritis and osteophytic spurs. The presence of pain in 50% of cases. Another provocative test is the biceps resistance test (Speed test), in which forward flexion of the shoulder (elbow extended and forearm supinated) carried out against resistance produces pain in the bicipital groove. The specificity of these tests is limited in the presence of impingement and rotator cuff disease.

Diagnostic Testing

Radiology. Radiographic findings usually are unremarkable, and the confirmatory test of choice is MRI. ED point of care ultrasound can be used to identify presence or absence of tendon in bicipital groove, and fluid within the sheath.

Management. The injured arm should be immobilized in a sling with the elbow in 90 degrees of flexion. The patient should be referred to an orthopedic surgeon for further evaluation and treatment within 72 hours. Surgical repair is a consideration in young, active persons. In older patients, conservative therapy (range-of-motion and strengthening exercise) is preferred because the cosmetic deformity is minimal and the mild functional loss usually is acceptable.

Subluxations and Dislocations of the Biceps Tendon

Subluxations and dislocations of the biceps tendon usually are associated with a congenitally shallow bicipital groove or articular (attritional) tears of the coracohumeral and transverse humeral ligaments. The patient reports a snapping sensation in the upper arm with abduction and external rotation. External and internal rotation of the abducted shoulder shows dislocation and relocation of the tendon. With complete dislocation, the arm may reflexively drop to relocate the tendon. These conditions may require operative repair and should be referred to an orthopedist.

Calcific Tendinitis

Pathophysiology. Shoulder calcific tendinitis affects up to 10% of the population and frequently is encountered in the ED. The condition affects people aged 40 to 60 years old and is painful in 65% of patients. Calcific deposits occur primarily in the supraspinatus tendon near its attachment to the greater tuberosity. Women are more often affected than men, and 10% of the patients have bilateral deposits.

Clinical Features. The clinical presentation can be divided into silent, subacute, and acute phases based on the physical characteristics of the calcific deposits and the nature of the inflammatory response within the tendon and subacromial bursa. The painful arc syndrome (see Fig. 46.31) is a hallmark of the subacute phase of calcific tendinitis. Enlargement and softening of the deposit lead to narrowing of the subacromial space, resulting in impingement under the acromial arch.

A severe inflammatory reaction within and around the deposit produces the acute phase of calcific tendinitis. Often there is a precipitating history of atraumatic repetitive motion (eg, swinging a tennis racket or moving bales of hay). The patient is in severe pain and holds the arm close to the chest. Active and passive range of motion is severely limited. The shoulder is warm and extremely tender to the touch. Severe pain is related to increased intratendinous pressure, and spontaneous rupture of the deposit into the subacromial bursa can be associated with dramatic relief of symptoms.

Diagnostic Testing

Radiology. Radiographs show calcific deposits in the involved tendon (Fig. 46.33). Bedside ultrasound can also identify location of calcific deposits (Fig. 46.34).

Management. The acute phase should be treated with sling for comfort, an antiinflammatory dose of an NSAID, and avoiding offending activities. Refer patients to primary care or sports medicine clinic, because they may benefit from subacromial bursa steroid injections, or needle lavage procedures to maximize conservative therapy before considering surgical removal.
Adhesive Capsulitis

**Principles.** Adhesive capsulitis (“frozen shoulder”) is a specific diagnostic entity characterized by an idiopathic inflammatory reaction within the capsule and synovium of the GHJ. The inflammatory reaction results in the formation of adhesions within the capsule and inferior axillary fold, leading to restricted active and passive range of motion. Adhesive capsulitis should be differentiated from other, more common causes of the painful stiff shoulder (eg, calcific tendinitis, rotator cuff tear, osteoarthritis, or trauma), which may be associated with decreased range of motion. Any condition associated with prolonged disuse of the arm can result in capsular contraction, including immobilization for painful intrinsic shoulder conditions such as after a mastectomy or a distal upper extremity injury (eg, Colles’ fracture).

**Clinical Features.** The typical patient is a woman 40 to 60 years old. The nondominant arm usually is affected, and the patient has trouble with the activities of daily living. The pain often is severe at night and localized over the deltoid area. As the condition progresses, there is uniform limitation of all glenohumeral movement. On passive testing of external rotation, a sense of mechanical restriction of joint motion can often be appreciated. Shoulder radiographs usually are normal in appearance if no associated pathologic condition is present.

**Management.** The best form of therapy is preventive in nature. Prolonged shoulder immobilization is to be avoided, and early motion encouraged in all instances (see Fig. 46.10). Treatment of adhesive capsulitis in the ED consists of anti-inflammatories and referral to a sports medicine provider or orthopedic surgeon. Initial therapy is conservative and consists of a gentle assisted exercise program along with an intra-articular steroid injection. Surgical treatment, including manipulation under anesthesia and arthroscopic capsular release, is reserved for patients who fail to improve with nonoperative treatment for at least 6 months.

**Injection Therapy**

The local injection of corticosteroid preparations has long been used in many painful conditions that affect the shoulder, including rotator cuff tendinitis, subacromial bursitis, calcific tendonitis and adhesive capsulitis. Ultrasound guidance is improving accuracy but unclear of a clinical improvement compared to landmark based treatment for subacromial injections. Although advocated for relieving the inflammatory reaction, corticosteroid injections in general do not alter the underlying disease process, and there is no evidence that they are superior to short courses of anti-inflammatory doses of NSAIDs. Systemic complications are rare after local injection therapy, although diabetics may experience elevated glucose levels. Site-specific complications include articular cartilage damage, tendon weakening or rupture, and subcutaneous atrophy. Direct tendon injection is particular hazardous, and there is a high failure rate for rotator cuff repairs when patients have received more than three preoperative subacromial injections. Corticosteroid injection treatments generally are deferred to outpatient providers (primary care, sports medicine, or orthopedic practitioners).

CHAPTER 46: QUESTIONS & ANSWERS

46.1. Which of the following represents a true orthopedic emergency?
   A. Anterior glenohumeral dislocation
   B. Anterior sternoclavicular dislocation
   C. Biceps rupture
   D. Posterior glenohumeral dislocation
   E. Posterior sternoclavicular dislocation

   Answer: E. Posterior sternoclavicular dislocations can be associated with life-threatening injuries within the superior mediastinum and intrathoracic cavity; therefore, they are considered true orthopedic emergencies and should be reduced expeditiously.

   Reported complications associated with posterior sternoclavicular dislocations include compression or lacerations of the great vessels, tracheal compression, pneumothorax, thoracic outlet syndrome, tracheoesophageal fistula, and injury to the brachial plexus.

   46.2. A 30-year-old patient presents complaining of right shoulder pain and limited range of motion. On physical examination, you note that the shoulder has a "squashed off" appearance and is held in abduction and external rotation. The patient is unable to adduct the arm or...
internally rotate without severe pain. What is the best way to manage this patient without the aid of other emergency department (ED) personnel?

A. Anderson method  
B. Hippocratic method  
C. Kocher maneuver  
D. Milch technique  
E. Traction/countertraction method

Answer: D. The ideal method for reduction of an anterior shoulder dislocation should be simple, quick, and effective; require little assistance; and cause no additional injury to the shoulder. It is wise to be familiar with several techniques of reduction because none is uniformly successful. The Milch technique allows for reduction by a single practitioner, and it can be attempted without procedural sedation. More traditional techniques, such as the Hippocratic method (traction with the foot in the axilla) and the Kocher maneuver (leverage, adduction, and internal rotation), are no longer recommended because of a high incidence of associated complications (axillary nerve injury, humeral shaft and neck fractures, and capsular damage). Traction/countertraction requires two people to reduce the shoulder, and there is no reduction technique called the Anderson method.

46.3. Urgent orthopedic consultation is recommended for which type of clavicle fracture?

A. Greenstick fracture  
B. Minimally displaced midclavicular fracture  
C. Type I lateral clavicle fracture  
D. Type II lateral clavicle fracture  
E. Type III lateral clavicle fracture

Answer: D. Type I lateral clavicle fractures are stable and minimally displaced because the coracoclavicular ligaments are intact. Type II fractures are associated with a torn coracoclavicular ligament and have a tendency to displace because the proximal fragment lacks any stabilizing forces. Type III injuries involve the articular surface. More urgent orthopedic consultation (before 72 hours) is recommended for type II lateral clavicle fractures, because these fractures have up to a 30% incidence of nonunion and may benefit from surgical repair.
Together, the pedicles and lamina form the neural arch, which, and the posterior aspect of the vertebral body are the pedicles. Processes are the lamina, and between the transverse processes each vertebral body has bilateral transverse processes and a route for the exit of spinal nerves. Between the vertebral bodies are the intervertebral discs, which provide elasticity and stability to the spine. Each disc is comprised of the outer annulus fibrosis, a ring of fibrous tissue, and the inner nucleus pulposus, a collagenous substance. The vertebral bodies and discs are connected by the PLL and the ALL. The ALL prevents hyperextension of the spine, whereas the PLL limits flexion of the spine. The spinous processes are connected by the supraspinous and interspinous ligaments. The ligamentum flavum connects the lamina posteriorly and helps maintain disc tension. The intertransverse ligament connects transverse processes on either side of the spine and limits lateral movement. Finally, the iliolumbar ligament stabilizes the lumbosacral joint.

Movements of the spine are governed by extensor muscles, found in the back—forward flexors, which are the abdominal wall muscles and the psoas and iliacus; lateral flexors, which are the quadratus lumborum assisted by abdominal wall muscles; and rotators, which are really the extensors and lateral flexors used unilaterally.

The spinal cord runs continuously from the foramen magnum to the L1 to L2 interspace. The spinal cord may sometimes be as low as L3. At this point, it splits into the cauda equina. It is surrounded by three membranes—the tough dura mater, and the more delicate arachnoid and pia mater (the leptomeninges). The epidural space, between the bony vertebral canal and the dura, contains connective tissue padding and the spinal venous plexus. The dural sac ends between S1 and S3. The dura also protects the spinal nerve roots as the nerves exit the spine. Between the arachnoid and pia mater cerebrospinal fluid bathes the spinal cord. At each level of the spine, nerves exit the cord and the cauda equina just below the correspondingly numbered vertebral body, for example L1 nerves exit bilaterally just below the L1 vertebral body. There are twelve thoracic nerve pairs, five lumbar nerve pairs, and five sacral nerve pairs. The spinal nerves give rise to sinuvertebral nerves, which provide sensory innervation to the meninges, the periosteum, and the PLL and ALL. The discs themselves have little innervation.

Pathophysiology

Uncomplicated Back Pain

In as many as 85% of patients, no pathologic cause for back pain can be identified. In these patients, pain is presumed to be from the soft tissue structures supporting the spine, primarily muscles and ligaments. Sprains and strains of the thoracic and lumbar paraspinal muscles can occur, as can ligamentous strain. These patients typically have localized pain and no radiation of pain or paresthesias to the lower extremities.1
Nerve Root Syndromes

Nerve root syndromes occur when there is compression or irritation of the nerve root, leading to pain, which often radiates down a leg, and paresthesia. There are multiple possible etiologies for nerve root syndromes.

As one ages, intervertebral discs desiccate and degenerate and the nucleus pulposus herniates outward, compressing the nerve root as the nerve exits the foramen.

Herniations tend to occur mainly at the L4 to L5 and L5 to S1 levels. This is because most flexion and extension of the spine occurs at the lumbosacral joint and to a lesser degree at L4 to L5. Additionally, the PLL is weak at this level of the spine. Disc herniation accounts for only 4% of acute back pain cases. Approximately 95% of patients with disk herniation have sciatica. Thus, only about 1 out of 500 patients with acute back pain but without sciatica symptoms will have a herniated disc as the cause.

The annulus fibrosis may tear without a true herniation of the nucleus pulposus. This can result in nerve root irritation rather than a true compression syndrome, and pain may radiate down the leg but not below the knee.

Although most disc herniations are posterolateral, discs sometimes herniate centrally, at the level of the cauda equina, causing severe compression of multiple nerve roots, resulting in cauda equina syndrome (CES). This results in spinal cord compression below the termination at the conus medullaris and loss of function of the lumbar plexus. This presents symptomatically as back pain that radiates to both legs, saddle anesthesia, and loss of bowel or bladder function. Saddle anesthesia involves the S3, S4, and S5 dermatomes, and it manifests clinically by numbness or tingling to the perineum, anus, and genitalia. Decreased rectal muscle tone causes loss of bowel function. Bladder dysfunction generally takes the form of incontinence to urine, which may manifest as overflow incontinence as a result of urinary retention. CES may also be caused by compressive lesions other than a herniated disc, including severe spinal stenosis, malignancy, infection, hemorrhage, or fracture.

Nerve compression can also be caused by spinal stenosis. Aging causes the disc space to narrow but also deteriorates the joints in the spine. Osteophytes form at the facet joints, and the ligmamentum flavum calcifies. These changes lead to narrowing of the neural foramina and the central canal with nerve root compression from osteophytes and increased intrathecal pressure in the narrowing canal. Pain is often bilateral, unlike impingement from a herniated disc. It also results in leg pain that typically worsens with walking that can be temporarily relieved if the person flexes forward slightly at the waist, relieving pressure on the nerve root, allowing further ambulation for a short period of time. This is known as the pseudolocalization sign.

Spinal epidural abscess causing CES or other nerve root symptoms is a rare but an important emergency. An abscess develops in the epidural space, usually from hematogenous spread of bacteria (often staphylococcal species), related to intravenous (IV) drug use or a recent tattoo. Patients can also develop epidural abscess from direct inoculation, such as an epidural steroid injection or recent spinal surgery. An epidural hematoma may present similarly, usually resulting from instrumentation of the epidural space or recent surgery, although it can occur spontaneously in a patient taking anticoagulants.

Skeletal Causes

Fractures may occur in any part of the spine secondary to trauma (see Chapter 36). Although a significant amount of force, either direct, axial loading, or flexion/distraction injury, is required to fracture a normal spine, patients with osteopenia secondary to age or chronic steroid use may sustain a fracture with little to no trauma. The incidence of vertebral compression fractures increases with advancing age. Even with the advancing age of general population, vertebral fracture accounts for less than 5% of acute back pain. In patients older than 50 years old, compression fracture may be the cause of sudden onset of acute back pain. Compression fracture may occur without trauma or injury. Spontaneous fractures generally present as compression fractures of the thoracic or lumbar vertebral bodies, whereas traumatic fractures may occur in any bony part of the vertebral column. Fractures may present with or without radicular symptoms, depending on the location of the injury and impingement on the spinal canal or nerve roots by a fracture fragment.

Like epidural abscess, osteomyelitis of the spine can be caused by hematogenous spread by bacteria. Pain is caused by inflammation of bone and periosteum and may or may not be associated with other manifestations of infection, such as fever. Again, IV drug use is a risk factor, as is direct bacterial infection from spinal surgery. Tuberculosis can also be a cause of osteomyelitis of the spine (Pott's disease).

Cancer in the spine is usually a metastatic lesion from another source, but primary bone tumors in the spine can also occur. Primary tumors are usually found in patients younger than 30 years old and involve the posterior vertebral elements. Primary spinal tumors include multiple myeloma, Ewing's sarcoma, and osteosarcoma, but primary lesions are 25 times less common than metastatic disease. Metastatic tumors more typically involve the vertebral body. Unlike many other causes of back pain, metastatic spinal lesions are more likely to be found in the thoracic spine (about 70%) than in the lumbar vertebrae. Metastasis is usually by the hematogenous route, and multiple levels are often involved. Lung and breast cancers make up over 50% of metastatic spinal lesions. Lymphoma, melanoma, cancers of the gastrointestinal (GI) tract, prostate, and kidney, and multiple myeloma may also present as metastatic spinal lesions. Of note, intramedullary and extradural metastases may also occur but are less common than bony metastases.

Skeletal back pain may also be caused by nontraumatic congenital or acquired abnormalities of the spine. Spondylolisthesis, or slippage of one vertebral body on another, causes back pain when the displacement is backward (retrolisthesis) but not when it is forward (anterolisthesis). Spondylolisthesis is usually the result of degenerative changes but may follow a traumatic event. Facet arthropathy, also a result of aging, may also be a cause of back pain. Inflammatory arthropathies, such as ankylosing spondylitis and rheumatoid arthritis, may cause the same changes in the spine as osteoarthritis and may also result in pathologic fractures.

CLINICAL FEATURES

History

A thorough history and a directed physical examination will, in most cases, guide the clinician to the correct diagnosis and will allow differentiation between simple musculoskeletal pain and more sinister diagnoses. The patient is asked to describe the current episode: onset; duration; severity; character of the pain (burning, shooting, dull or sharp, constant or intermittent); location, including presence of any abdominal or flank pain; and radiation. Radiation of the pain to the lower extremity is another important feature of the history. Pain that radiates below the knee is more likely to be radicular. Pain that does not radiate is more likely musculoskeletal in origin. Pain that radiates, but not below the knee, may suggest an annular ligament tear.

Aggravating factors are also important. Pain that increases with increasing intrathecal pressure (such as, coughing, sneezing, or bearing down with bowel movements) increases the likelihood of
a radicular or spinal cause. Pain that is worse with walking or prolonged standing, or pseudoclaudication, particularly if relieved by bending forward, suggests spinal stenosis. Pain that is worse in the mornings and improves through the day suggests a rheumatic etiology.

The patient is asked about neurologic findings (such as, numbness or weakness), pain in other parts of the spine, and whether there is bowel or bladder dysfunction. Next, seek the nature and timing of any prior episodes of back pain and any history of back trauma, malignancy, systemic symptoms (fever, chills, malaise, nausea, generalized myalgia), spinal surgery or procedures (eg, epidural injection), and anticoagulant use. Medications are reviewed, particularly corticosteroid use, which may point to an underlying inflammatory cause, and also can cause osteopenia with increased likelihood of fracture. Family history is rarely contributory, but history of autoimmune inflammatory diseases and malignancy may be helpful.

Physical Examination

The patient is undressed and placed in a gown. Inspection of the overlying skin for changes such as erythema, warmth, or swelling is supplemented by a general observation of the patient's wellness, degree of discomfort, and presence of any generalized skin changes, such as jaundice, rash, or multiple bruises. The patient ambulates and the gait should be observed. Range of motion includes flexion and extension at the waist (entire spine), lateral flexion (mostly thoracic spine), and rotation (exclusively thoracic spine). This is also a good time to examine for scoliosis, which may be longstanding or acute secondary to muscle spasm.

Next, palpation in the location of the pain may identify areas of maximal tenderness or the presence of muscle spasm. Strength testing of the lower extremities is best done with the patient standing. The patient is instructed to flex both hips and knees, assuming a partial sitting position, then to lift one leg briefly, then the other. Walking on heels and on toes (while holding the examiner's hands) requires full plantar and dorsiflexion strength, because the entire body weight is carried on a single extremity. If the patient is not able to comply with this testing because of pain, strength testing can be performed with the patient lying down, but it is not as reliable. Sensory testing is done with the patient lying down or sitting. Testing should include the upper extremities, because some conditions, such as spinal stenosis, may occur at multiple levels of the spine and may involve the cervical spine as well. A thorough neurologic examination can help the clinician determine if multiple levels of the spine need to be imaged.

Straight leg raise and crossed leg raise tests are important in determining if the pain is radicular. The straight leg raise test is more sensitive but less specific than the contralateral straight leg raise test for the diagnosis of radiculopathy due to disc herniation. The straight leg raise test is performed as follows:

- With the patient supine and legs extended, the examiner raises the each leg, flexing at the hip with the knee in extension.
- The patient is completely passive for this examination, and the quadriceps should not be engaged.
- This can be determined by noting that the patella can be moved freely move side to side.
- A positive result is pain radiating from the back to a point below the knee of the raised leg at 30 to 40 degrees of elevation. A positive result predicts L5 or S1 radiculopathy with a specificity of approximately 90% and a sensitivity of 50% or lower.

Because these two discs are implicated in 95% of disc herniations, this is a highly useful test, and a negative result is reassuring in ruling out disc pathology. Radiation of pain from the back to the area of the posterior knee or above is a nonspecific finding of no clinical value.

The contralateral leg raise test is performed in an identical manner. A positive finding is pain that radiates below the knee of the contralateral leg (the leg that is not being raised). The sensitivity of this test for disc herniation is poor, below 25%, but specificity approaches 100%. This makes a positive test result strongly suggestive of disc pathology at the L5 or S1 levels. If one has a positive straight leg raise test, a positive contralateral straight leg raise test can be considered confirmatory of the presence of a ruptured disc. If the contralateral straight leg raise is positive with a negative straight leg raise test, disc herniation is still highly likely due to the high specificity of the contralateral test.

Patellar and Achilles deep tendon reflexes should be elicited and the plantar reflex assessed. Hyperreflexia, clonus, or a Babinski sign (positive plantar reflex) suggests upper motor neuron pathology, such as a cord impingement or malignancy.

Perineal sensation and anal sphincter tone are assessed in patients with bilateral symptoms or findings, gait disturbance, severe pain, complaints of saddle anesthesia, or bowel or bladder dysfunction. Bladder dysfunction is evaluated by post-void ultrasonographic measurement of bladder volume. A completely normal bladder should have about 20 cc of residual urine after voiding, and anything over 100 cc is considered abnormal. If bedside ultrasound is not available, post-void residual is measured by in-and-out urinary catheterization.

Because pain from abdominal or pelvic pathology often radiates to the back, a thorough abdominal examination, including assessing for costovertebral angle tenderness and, where indicated, a prostate or gynecologic examination should be performed to rule out non-musculoskeletal causes of low back pain.

DIFFERENTIAL DIAGNOSES

Table 47.1 lists the various causes of low back pain along with findings on the history that point toward the specific cause of back pain. In constructing a differential diagnosis, the clinician incorporates history and physical examination finding, particularly whether there is evidence of a nerve root cause for the pain, or findings to suggest infection or malignancy. Radicular pain is most often due to true herniated discs. Classic presentation includes decreased sensation in a dermatomal distribution corresponding to the level of the involved disc along with motor weakness and reflex loss (Table 47.2). However, herniated discs can present with only a positive straight leg raise test (see earlier discussion).

DIAGNOSTIC TESTING

Laboratory Testing

Laboratory testing is rarely indicated for low back pain. When spinal epidural abscess is suspected, prompt imaging is required, although a white blood cell (WBC) count, erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP) should be obtained in parallel with the imaging plan. The WBC count is often obtained when infection is suspected but is neither sufficiently sensitive nor specific to confirm or exclude any particular diagnosis. The presence of an elevated ESR significantly increases the suspicion for a spinal epidural abscess, osteomyelitis, or discitis. Marked elevations in the ESR are more often due to infection than other causes, but noninfectious disorders such as malignancy, chronic diseases, inflammation, trauma, and tissue ischemia are also common etiologies. ESR values of over 100 mm/hour are most likely due to infection, whereas lower values suggest myriad causes, of which infection is just one. CRP is both less sensitive and specific than ESR, but it may add some diagnostic information when elevated. Markedly elevated levels of CRP are strongly associated with infections with values in above 10 mg/dL (100 mg/L).

### Indications for Advanced Imaging Studies

Most patients with back pain require neither plain radiographs nor advanced imaging. Routine imaging for low back pain is not associated with an improvement in patient outcomes. Even when abnormalities are found, they are often incidental and not the cause of presenting symptoms. Imaging in the setting of acute pain should be reserved for patients with suspected diagnoses that would necessitate emergency management. Signs, symptoms, and historical features that should lead the clinician to consider imaging studies are provided in Box 47.1.

#### Imaging Studies

In general patients with nontraumatic low back pain with a normal neurological examination do not need plain radiographs in the ED. Clinicians may obtain plain radiographs when there is concern for occult spontaneous compression fractures in patients with nontraumatic back pain who have osteopenia or are taking chronic steroids. If ESR or CRP tests are elevated, plain films should not be obtained, and one should proceed directly to advanced imaging. In cases where there is a history of low energy traumatic injury (such as, ground level fall or low speed motor vehicle collision), plain radiographs of the affected area of the spine are sufficient to identify or exclude significant fractures. Elderly patients are at particular risk for occult fractures with minor trauma, and the clinician should obtain plain films in the ED when localized pain or tenderness is present, even with low energy mechanisms. Anteroposterior and lateral views of the thoracic and lumbar spine are usually sufficient in the ED to evaluate for acute fractures. Oblique views show the pars interarticularis in profile and may help in the diagnosis of spondylolysis. In general, oblique views do not add additional information and significantly increase the dose of radiation. These views, therefore, are not recommended for routine evaluation. Flexion/extension views may be helpful in patients who have had surgical fusion procedures to evaluate for slippage or fracture of hardware. Plain radiographs of the chest may also be helpful, particular in the setting of thoracic back pain, because rib fractures can be detected and may be the cause of pain referred to the back. The sensitivity, specificity, and diagnostic accuracy of plain films and advanced imaging techniques for spine trauma are discussed in Chapter 36. In nontrauma cases, advanced neuroimaging is indicated when localizing signs and symptoms suggest possible epidural abscess, mass, or hematoma, osteomyelitis or discitis, or CES, or when

#### Plain Radiographs

Coagulation testing is indicated for patient taking long-term anticoagulants. If the prothrombin time (PT) or international normalized ratio (INR) is excessively elevated in the setting of low back pain complaints, one should consider a spontaneous epidual or retroperitoneal bleed.

Urinalysis may also be helpful when the problem is not clearly musculoskeletal, because low back pain in women can be of pelvic origin. A urine pregnancy test should be obtained when imaging is indicated in a woman of childbearing age or if back pain is felt to be of pelvic origin.

---

---
there are new significant neurological deficits or unexplained neurological findings. Computed tomography (CT), magnetic resonance imaging (MRI), and CT myelogram are the most commonly used modalities, and each is further discussed in the following sections.

Computed Tomography

CT is preferable to MRI for bony anatomy abnormalities. If a fracture is present on plain films, CT can better delineate the nature and extent of the fracture. In patients with higher pre-test probability of fracture (ie, those with a significant injury mechanism, on chronic steroid therapy, or with point tenderness directly on a thoracic or lumbar vertebra), the clinician should omit plain radiographs and proceed directly to CT scan. In a multi-trauma patient undergoing CT scans of the chest and abdomen, views of the thoracic and lumbar spine can be reconstructed from these studies, and dedicated plain films are not necessary. CT has superior sensitivity for detecting abnormalities of cortical bone over MRI, which cannot directly visualize cortical bone. Therefore, when bony injury or lesions are suspected, CT is preferable over MRI. The converse is true when soft tissue pathology, including spine and nerve roots, is suspected.

Magnetic Resonance Imaging

MRI is the test of choice for evaluating the spinal cord and the spinal structures, including the canal, intervertebral discs, and soft tissue, including ligaments and epidural space. MRI defines the bony anatomy and visualizes soft tissues and neural structures, such as the conus medullaris and spinal nerve roots within the canal and neural foramina. It provides axial as well as sagittal views, which can demonstrate pathologic discs, ligaments, nerve roots, and epidural fat, as well as the shape and size of the spinal canal. MRI is both more sensitive and specific than plain radiographic studies for the detection of spinal infection and malignancy, and it is the modality of choice in back pain patients with elevated ESR or CRP. Emergent MRI is indicated for suspected CES, epidural hemorrhage, or history of malignancy with sudden onset or worsening of pain accompanied by new neurological findings. MRI helps delineate many etiologies of back pain, including epidural hematoma or abscess, herniated disc, ligamentous injury, and spinal stenosis, and it is the test of choice for diagnosing osteomyelitis. MRI may also help to determine the chronicity of a fracture. For example, if a plain film, or even CT, demonstrates a compression fracture but there was no inciting trauma or the history is unclear, MRI may help delineate whether the fracture is acute. However, for acute fractures, CT is still the imaging modality of choice. Contrast administration provides little additional information to the MRI and is unnecessary unless either new spinal symptoms arise postoperatively or there is a question of intraspinal infection or metastasis.

In evaluating for spinal cord lesions, the clinician must make a decision about which spinal levels to include. A thorough neurologic examination that includes upper extremities may be used to exclude the C spine from imaging, but it is important to remember that spinal processes (such as, malignancy or stenosis) can occur simultaneously in several levels, and the region of pain may not always correspond to the lesion causing a neurologic deficit. Cervical or thoracic spine lesions may cause lower extremity deficits. For this reason, consideration should be given to imaging the entire spine.

Computed Tomography Myelogram

Myelography is rarely performed in current practice and generally used in patients who need advanced imaging but are not able to have an MRI, such as those with implanted hardware (pacemaker, spinal hardware, deep brain stimulator) or retained metal fragments from previous surgery or injuries. Because of the theoretical increased risk of seizure during this procedure, emergency clinicians should be aware of medications the patient is taking that lower seizure threshold, such as tramadol. If on these medications, some centers require that they be held for 24 to 72 hours before the test can be performed. Clinicians should discuss medications with their consulting radiologist before ordering this test.

MANAGEMENT

Figure 47.1 presents and algorithmic approach to ED management of patients with low back pain based on physical and/or ancillary test findings.

Uncomplicated Back Pain

Initial therapy for uncomplicated back pain focuses on pain control to maximizing return to function. Treatment in the ED is directed at supportive care and symptomatic relief. In patients with mild to moderate pain and adequate function (can get up and down off the bed and walk unaided), initial therapy is an oral nonsteroidal antiinflammatory drug (NSAID) in analgesic doses (eg, ibuprofen 400 to 600 mg every 4 hours), or acetaminophen 1000 mg every 4 to 6 hours, if the patient is NSAID intolerant.11 For patients with severe pain or muscle spasm that significantly affects normal daily function and with a normal neurologic examination, oral analgesia with an NSAID, as mentioned earlier, is supplemented by an oral opioid medication, such as oxycodone 5 to 10 mg, with observation for improvement over a 2-hour period. There is no proven benefit of ongoing opioid analgesic therapy, and opioid prescriptions at discharge should provide coverage only for 24 to 72 hours to mitigate the acute pain and improve sleep, movement, and ambulation. Combination therapy with NSAIDs and opioids, as compared to NSAIDs alone, does not appear to improve functional outcomes or pain at 1-week follow-up.16,17 Similarly, there is no proven benefit of “muscle relaxant” medications, such as cyclobenzaprine or carisoprodol, and these agents have very significant side effect profiles. We do not recommend their use, either in the ED or as a discharge prescription. A benzodiazepine may be prescribed to supplement the analgesic regimen when the patient has failed an appropriate regimen or when the pain is causing substantial anxiety or sleep disturbance. Once the patient’s symptoms are improving, the patient is discharged on an appropriate pain regimen, guided by the results in the ED. Wherever possible, outpatient management should be achieved with NSAID medication alone, although some patients with severe pain may require a short course (3 days) of opioid medication as well.18

Bed rest is not recommended. Patients without sciatic symptoms benefit from staying active, and patients with sciatic symptoms are likely to experience no difference in pain from bed rest versus staying active.19

Early return to work, with or without activity restrictions, is associated with better long-term outcomes. Patients may also experience benefit from gentle stretching exercises. Physical therapy, although not associated with improved outcomes for uncomplicated back pain, is associated with improved patient satisfaction. A referral to physical therapy may be made in the ED or by the patient’s primary care physician.20 Seventy percent of patients achieve improvement within 1 week.21,22 Only about 10% of all patients have long-term issues, often because of functional overlay. Chronic back pain is more likely to develop in patients with psychiatric disorders, poor overall health status, and nonorganic signs. Development is not associated with demographic variables, prior episodes of back pain, or baseline pain levels.23
**Disk Herniation**

Herniated disks are commonly managed initially like lumbosacral strain with no imaging indicated and symptomatic treatment provided. Signs and symptoms that indicate the need for advanced imaging include new bowel or bladder dysfunction, new localized motor weakness, progressive leg weakness, or acute and substantial worsening of symptoms or findings in patients with known herniated discs or chronic back problems. Indications for emergent spine service consultation include rapidly progressive neurological symptoms or signs of acute cord compression, including CES.

**Nerve Root Pain**

Patients with nerve root or sciatic pain and no neurologic deficits should be treated similarly to those with uncomplicated back pain. Oral steroids do not improve recovery for unselected patients with acute back pain. However, there is evidence that the subset of patients with nerve root pain and acute radiculopathy benefit from a single pulse dose of 6 to 10 mg of IV dexamethasone in the ED. Alternatively, a 15-day course of a tapering dose of prednisone (60 mg, 40 mg, 20 mg daily for 5 days each) improves function but without improvement in pain.

**Epidural Abscess and Spinal Osteomyelitis**

Epidural abscess is a surgical emergency. Emergent spine surgery consultation should be obtained; or if not possible at the treating hospital, the patient should be transferred to a facility with spine surgery available. Empirical antibiotics should also be administered to cover suspected pathogens, usually *Staphylococcus*, *Streptococcus*, and gram-negative species. Because of increasing rates of methicillin-resistant *Staphylococcus aureus* (MRSA) infection, vancomycin should be included in the antibiotic regimen. Pseudomonal coverage should be considered when the infection is felt to be due to hematologic spread, particularly in diabetic patients and those with sickle cell disease. Antibiotics should be directed against the known pathogen if the culture or

*Fig. 47.1. Algorithmic approach to emergency department (ED) management of low back pain. CES, Cauda equina syndrome; MRI, magnetic resonance imaging; NSAID, nonsteroidal antiinflammatory drug; PCP, primary care physician; PVR, post-void residual.*
Gram stain of the aspirate is positive. Appropriate empirical parenteral regimens include:
- Vancomycin (30 to 60 mg/kg IV per day in two equally divided doses adjusted for renal function) for empirical coverage of MRSA
  plus
- Metronidazole (500 mg IV every 8 hours)
  plus
- Either cefotaxime (2 g IV every 6 hours), ceftriaxone (2 g IV every 12 hours), or ceftazidime (2 g IV every 8 hours); Ceftazi-
dime is preferable when *Pseudomonas aeruginosa* is considered a possible or likely pathogen.

In some cases, especially where MRI shows minimal cord impingement, conservative management with antibiotics alone and no surgery may be considered. Osteomyelitis also requires antibiotics with coverage for similar bacterial pathogens, along with surgical consultation. The need for surgery may be less emergent than with epidural abscess if there is no mass effect on the cord or purulent fluid collection. Whenever possible, antibiotic therapy should be delayed in stable patients until tissue cultures can be obtained. If tissue culture is not obtainable and in advance of tissue culture results, broad-spectrum empirical therapy should be administered. Empirical inpatient antibiotics commonly include:
- Inpatient treatment:
  - Nafcillin (2 g every 4 hours) for methicillin-sensitive *Staphylococcus aureus* (MSSA) coverage
  or
  - Vancomycin (30 to 60 mg/kg IV per day in two equally divided doses adjusted for renal function) for empirical coverage of MRSA
  or
  - Cefepime (2 g IV every 8 to 12 hours) for gram-negative and *Pseudomonas* coverage
- Outpatient treatment:
  - Ciprofloxacin (750 mg by mouth BID)
  or
  - Trimethoprim-sulfamethoxazole (1 double-strength tablet twice daily)

**Epidural Hematoma**

Although rare, the diagnosis of epidural hematoma should result in emergent spinal surgical consultation. Additionally, patients on anticoagulant should have their anticoagulation reversed as described in Chapter 114. Because of the danger of hematoma expansion, consultation should be obtained rapidly and all necessary steps taken to facilitate rapid operative intervention.

**Cauda Equina Syndrome**

CES, when suspected, requires rapid confirmation and, if confirmed, emergency decompression, usually by surgery, is the usual course of action. Emergency medicine and radiology departments should collaborate on the development of a CES imaging protocol that gives immediate priority to patients clinically suspected of CES and ensures the most rapid possible completion of MRI imaging and expert interpretation. Whenever possible, the emergency spine surgery consultation should be obtained in parallel with the ordering of the imaging study so that plans can be established in the event the diagnosis is confirmed by imaging. Although prompt surgery provides the best opportunity for a good outcome, some patients may not recover function even after decompressive surgery; and in patients with longstanding or chronic symptoms of CES, surgery may be deferred. Planning with respect to emergency surgical intervention occurs in consultation with spine surgery. Some clinicians initiate IV corticosteroid therapy when the diagnosis of CES is strongly suspected or confirmed; however, multiple clinical trials have failed to identify convincing evidence of greater or more rapid recovery of function with this practice. The risk of a single dose of corticosteroids is very low. We recommend that corticosteroids not be used in CES unless ordered by the treating spine surgeon.

**Malignancy**

If malignancy is diagnosed on plain film or advanced imaging but the patient is neurologically intact and pain can be well controlled, management may be continued as an outpatient. However, patients with compressive malignant lesions of the spine or spinal cord may benefit from emergent corticosteroids to reduce the severity of mass effect. A single dose of 10 mg IV dexamethasone is the steroid of choice, and it is administered when new neurologic findings suggest an acute compressive malignant lesion. However, the effects are transient, and surgical decompression may be required. Additionally, radiation oncology consultation is sought to determine whether emergency decompressive radiation therapy is indicated. This can be done in conjunction with oncology or surgical consultation.

**Fracture**

The management of acute traumatic spinal fractures is discussed in Chapter 36.

**DISPOSITION**

The vast majority of patients presenting to the ED with acute back pain will be discharged with symptomatic treatment and an appropriate follow-up plan. For most, follow-up with a primary care physician is adequate. If the patient has no radicular findings, then that the clinician should explain to the patient why imaging is not helpful and that the pain will likely resolve with conservative measures. Work notes may help patients limit heavy lifting or significant time on their feet. Patients should also be counseled that despite being provided medications, acute back pain is unlikely to resolve quickly and may take days or weeks to significantly improve. Setting an expectation for the time frame for improvement may reduce the likelihood of a quick return to the ED for unchanged symptoms. Patients with suspected radiculopa-
thy should also be given clear return precautions, including the development of weakness, inability to stand or ambulate, saddle anesthesia, or bowel or bladder dysfunction.

For those with back pain thought to be secondary to a compressive lesion (such as, a herniated disc) and non-emergent sensory or motor findings (see earlier discussion), follow-up should occur in 3 to 7 days with the primary care physician or a spine surgeon. This is the case for patients who did not have imaging, or imaging was performed but did not identify an urgent surgical lesion. When imaging is not obtained, the patient is counseled that imaging will not likely be required in future unless symptoms persist or worsen over several weeks. Studies of the benefits of interventions (such as, epidural steroid injection) have provided mixed results, but discussion of such therapy is the domain of the spine consultant on an outpatient basis.

Patients who require emergent surgical intervention for spinal epidural abscess, neoplasm, osteomyelitis, fracture, or other compressive spine lesions should be transferred to the care of a spine surgeon emergently, which may involve transfer to a tertiary care center.

Transfer may also be necessitated by the non-availability of MRI or CT myelography in patients in whom an emergent infectious or compressive etiology is strongly suspected. Patients
believed to have an epidural abscess or osteomyelitis should receive empirical parenteral antibiotics as detailed in Epidural Abscess and Spinal Osteomyelitis section earlier. Patients with findings consistent with CES or other compressive lesions due to malignancy should receive parenteral steroids prior to transfer if ordered by the receiving physician or the onsite consultant.

**KEY CONCEPTS**

- Most back pain presenting to the emergency department (ED) is benign, self-resolving with conservative therapy, and does not require imaging.
- Indications for emergent imaging include history of malignancy, new significant neurologic deficit, bowel or bladder dysfunction or saddle anesthesia, intravenous (IV) drug use, fever, immunocompromised state, chronic steroid use, and anticoagulant use.
- Metastatic disease is more common than primary tumors in the spine, and thoracic metastases are more common than lumbar metastases.
- Epidural abscess or hematoma, cauda equina syndrome (CES), spinal malignancy with compressive symptoms, and spinal osteomyelitis are indication for emergent surgical consultation or transfer to a center where emergent surgical consultation is available.
- Empirical parenteral antibiotics active against staphylococci, streptococci, and gram-negative bacilli should be administered for suspected epidural abscess. Antibiotics should be directed against the known pathogen if the culture or Gram stain of the aspirate is positive.
- Corticosteroids given as a single dose in the ED (10 mg dexamethasone) or as a 15-day tapering course after discharge (prednisone 60 mg, 40 mg, 20 mg daily for 5 days) may improve functional ability but do not improve pain for patients with nerve root findings related to disc herniation.
- Corticosteroids are of no proven benefit for patients with CES. We recommend that corticosteroids not be used for patients with suspected or known CES unless desired by the treating spine surgeon.

CHAPTER 47: QUESTIONS & ANSWERS

47.1. A 55-year-old man presents with the complaint of low back pain for 1 month. The pain is worse at night and is associated with a 10-pound weight loss. He denies any radicular symptoms. Which of the following is the most likely cause of this man's back pain?

A. Chordoma
B. Lymphoma
C. Multiple mieloma
D. Osteosarcoma
E. Sciatica

Answer: B. The patient’s subacute time course of back pain and worrisome finding of weight loss suggest a malignancy. Primary and metastatic bone neoplasms can cause back pain from tumor infiltration into the bone. Primary bone tumors, such as multiple myeloma, chordoma, Ewing’s sarcoma, and osteosarcoma, are 25 times less frequent than metastatic disease. Of the neoplasms, breast, lung, prostate, thyroid, lymphoma, and kidney are the most likely to metastasize to bone.

47.2. Which one of the following indicates a benign presentation of back pain?

A. Low back pain and fever
B. Low back pain and saddle anesthesia
C. Low back pain in a 6-year-old child
D. Low back pain with a negative sitting but a positive supine straight leg raise (SLR) test
E. Low back pain with post-void residual of 500 mL

Answer: D. A positive supine SLR test but a negative sitting SLR test suggests a nonphysiologic cause for the pain. Low back pain and fever suggest an epidural abscess or spondylitis. Saddle anesthesia and post-void residual greater than 100 mL are indicative of cauda equina syndrome (CES). Children complaining of back pain must be investigated. They may have spondylolysis with varying degrees of spondylolisthesis, Scheuermann’s disease (kyphosis and osteochondritis of the vertebral end plates), infectious diseases, or neoplastic etiologies.

47.3. The adult spinal cord usually ends at which level?

A. L1 to L2
B. L3 to L4
C. L5 to S1
D. S2 to S3
E. Coccyx

Answer: A. The spinal cord ends at around L2 in adults, lower in children. Remember that between individuals, there may be significant anatomic variance.

47.4. A 55-year-old man complains of low back pain when walking downhill that is relieved with walking uphill. His neurovascular examination is unremarkable except for decreased bilateral Achilles reflexes. What is the appropriate management of this patient?

A. Lumbosacral radiographs
B. Magnetic resonance imaging (MRI)
C. Pain management and bed rest
D. Pain management and emergent surgical consultation
E. Pain management and surgical referral for pseudoclaudication

Answer: E. This patient presents with typical complaints of spinal stenosis. Patients with spinal stenosis should be managed conservatively with pain medications. In the absence of alarming red flag findings, these patients do not require laboratory or radiographic studies in the emergency department (ED). These patients may be candidates for surgery if they show any of the following conditions: progressive neurologic deficit, progressive reduction in ability to walk secondary to pseudoclaudication, evidence of cauda equina syndrome (CES), or intractable pain.
47.5. Which of the following statements regarding cauda equina syndrome (CES) is false?
A. Hallmarks are saddle anesthesia and urinary retention
B. Is often caused by a central disk herniation
C. Is most often associated with a post-void urinary residual of 75 mL or less
D. Requires emergency surgical decompression
E. Usually compresses bilateral nerve roots

Answer: C. The most consistent examination finding in CES is urinary retention. With a high sensitivity of 90%, the patient is unlikely to have this disease process if his or her post-void residual urine volume is less than 100 to 200 mL. Saddle anesthesia (sensory deficit over the buttocks, upper posterior thighs, and perineal area) is frequently an associated finding, with a sensitivity of 75%. In 60% to 80% of cases, the rectal examination reveals a decreased sphincter tone.

47.6. A 42-year-old man presents to the emergency department (ED) with a 12-day history of low back pain after an episode of heavy lifting at work. He reports bilateral low back pain at the level of the iliac crests. He denies sensory or motor symptoms. He also denies bowel or bladder dysfunction. His neurologic examination is normal. For this patient, which are the most important treatments and recommendations?
A. Lumbar MRI
B. Lumbar MRI, complete blood count (CBC), and erythrocyte sedimentation rate (ESR)
C. Obtaining lumbar radiographs with anteroposterior, lateral, and oblique views
D. Placement on strict bed rest for 4 weeks
E. Treatment with symptomatic medication and return to light activity

Answer: E. The patient most likely suffers from idiopathic low back pain. This is also commonly called acute lumbosacral strain. Most patients with this injury should not be placed on bed rest and should be allowed to return to normal activity, possibly with some restrictions. The patient has a relatively short history of low back pain with clear onset around an episode of lifting. Given a lack of concerning historical or examination findings, the patient does not require imaging at this time. Blood work would not be of help in evaluating the patient, because he lacks history or examination findings consistent with spinal infection.

47.7. A 35-year-old woman presents with a 3-day history of severe right lower extremity pain associated with mild low back pain. Her neurologic examination is normal except for a positive straight leg raise (SLR) test on the right and a negative cross straight leg raise (CSLR) test on the left. What is the most likely source of this patient’s symptoms?
A. Acute lumbosacral strain
B. Ankylosing spondylitis
C. Lumbar disk herniation with radiculopathy
D. Spinal epidural abscess
E. Spinal malignancy

Answer: C. Patients with herniated lumbar disks often present with radicular leg pain that overshadows the complaint of back pain. It is very common for a patient with lumbar radiculopathy to have no clear motor or sensory deficit but have exacerbation of leg pain with SLR testing. The SLR has high sensitivity but low specificity. In contrast, the CSLR test has high specificity but low sensitivity. Given this, it is common for the patient with lumbar disk herniation to have a positive SLR but negative CSLR. The reverse is very uncommon. Diagnoses (such as, spinal epidural abscess and spinal malignancy) usually present with prominent low back pain that is more significant than extremity pain.

47.8. A 68-year-old man presents with a 5-week history of worsening low back pain. He reports mostly midline spinal pain with occasional radiation into both lower extremities. Two weeks before the onset of his pain, he was discharged from the hospital after an inpatient stay for pneumonia. On examination, he has intact lower extremity motor and sensory function but tenderness to percussion over the lumbar spine. Initial evaluation of the patient is most likely to reveal which of the following?
A. Lumbar computed tomography (CT) showing degenerative spondylolisthesis at L4 to L5
B. Lumbar magnetic resonance imaging (MRI) showing unilateral L4 to L5 disk herniation
C. Lumbar MRI showing very large central disk herniation at L4 to L5 with compression of the cauda equina
D. White blood cell (WBC) count of 9000 and erythrocyte sedimentation rate (ESR) of 58
E. WBC count of 22,000 and ESR of 4

Answer: D. The patient’s history is suspicious for spinal epidural abscess. He is at higher risk because of his age and recent infection. In addition, the patient has tenderness with percussion of his spine. Patients with epidural abscess usually have an ESR elevated above 20 mm/hr. However, it is not uncommon for them to have a normal or only mildly elevated WBC count. It would be uncommon for the patient to have an elevated WBC count but normal ESR. Lumbar disk herniation is rarely associated with spinal tenderness to percussion. A large central disk herniation with bilateral nerve root compression would likely present with lower extremity symptoms. Degenerative spondylolisthesis at L4 to L5 would likely be an asymptomatic problem.

47.9. A 63-year-old man presents with a 9-month history of progressive low back pain with ambulation. He reports significant pain in his buttocks and posterior thighs when he walks distances greater than 25 meters. He says the pain is partially relieved when he flexes forward and completely relieved by recumbency. He reports the pain is not relieved if he stops walking but remains standing. On neurologic examination, he has intact lower extremity strength but diminished Achilles reflexes bilaterally. Other likely findings include which of the following?
A. Diminished posterior tibial and dorsalis pedis pulses
B. Lumbar magnetic resonance imaging (MRI) revealing right L5 to S1 disk herniation
C. Lumbar MRI revealing spinal stenosis at L4 to L5 and L5 to S1
D. Normal lumbar MRI
E. Thoracic MRI revealing significant T5 to T6 disk herniation with spinal cord compression

Answer: C. The patient presents with classic findings of spinal stenosis and neurogenic claudication or “pseudoclaudication,” including relief with flexing forward and recumbency. Persistence of pain with standing despite having stopped ambulating is also indicative of neurogenic claudication, as are diminished Achilles reflexes. Diminished pulses are indicative of vascular claudication. Pain from vascular claudication is generally relieved if a patient stops walking but remains standing. Unilateral disk herniation does not usually present with bilateral lower extremity symptoms. Spinal cord compression from T5 to T6 disk herniation would cause myelopathy and generally present with gait unsteadiness and hyperreflexia but not pain.
Epidemiology

The majority of high-energy pelvic ring injuries are caused by motor vehicle collisions (MVCs), motorcycle crashes, pedestrians being struck by motor vehicles, and falls from height. Mortality of patients with pelvic fracture ranges to over 20%; in studies of large cohorts of trauma patients, the presence of pelvic fracture has consistently shown to be an independent risk factor for death. Patients with pelvic fractures who present with shock on arrival to the hospital have mortality rates of up to 50%. Increased age, the presence of shock at the time of arrival, presence of multisystem injuries, and the need for transfusion increase the risk of death.

Despite advances in motor vehicle safety design, MVCs continue to be a major cause of pelvic fracture, with lateral impact collisions remaining the most prevalent mechanism. The widespread use of front impact airbags has had little protective effect on these lateral collisions. However, side-impact airbags have been shown to reduce the risk of death in lateral impact MVC by 30% to 40%. Current research suggests that side impact airbags reduce the risk of head injuries by 30%, but they have minimal protective effect on thoracic or pelvic injuries. Newer technology knee bolster airbags are claimed to reduce the risk of knee-thigh-hip injuries; however, there is not enough evidence to date to know whether they are effective or not.

Anatomy

Detailed descriptions of pelvic anatomy can be found in standard anatomy texts. This section focuses on the relevant anatomy essential to understanding pelvic injuries.

Bony and Ligamentous Anatomy

The pelvic ring is made up of right and left innominate bones and the sacrum. The innominate bones consist of the pubis, ischium, and ilium (Fig. 48.1). The bony pelvis provides protection for its visceral contents, serves as attachment points for muscles, and transmits weight from the trunk to the lower limbs. The main weight-bearing forces are transmitted through the posterior wall of the pelvis, called the posterior arch, which is composed of thick bone and ligaments. The rich network of major arteries, veins, and nerves that course in front of the posterior arch can be injured concomitantly with forces responsible for bony injuries.

Knowledge of the ligamentous attachments of the pelvic ring is crucial to understanding how stability is maintained or disrupted in pelvic injuries. Pelvic stability is maintained by ligaments as well as the muscles and fascia that make up the pelvic floor. Anteriorly, the symphysis pubis provides the major mechanical stability. Posteriorly, a composite of strong ligaments—the sacrospinous, sacrotuberous, iliolumbar, and anterior and posterior sacroiliac ligaments—maintains the integrity of the posterior arch (Fig. 48.2). These ligaments are the primary stabilizing force of the posterior pelvis. Disruption of these ligaments is the primary cause of a mechanically unstable pelvic fracture.

Vascular Anatomy

Most of the blood supply to the pelvis comes from the left and right internal iliac arteries. The internal iliac arteries course at the level of the sacroiliac joints. The various arteries that derive from the internal iliac arteries initially run in close proximity to the posterior pelvic arch and eventually Anastomose extensively with one another, forming a rich collateral network (Fig. 48.3). The superior gluteal artery is the largest branch and is commonly injured in fractures of the posterior pelvic arch. The obturator and internal pudendal branches are often injured in fractures involving the pubic rami.

The venous system also has many collateral branches but does not have valves, which allows bidirectional flow. The veins are arranged in a plexus that adheres closely to the pelvic walls. Because these veins are thin-walled, they do not have the ability to constrict in response to damage. This anatomic arrangement of the arteries and veins accounts for the hemorrhage often associated with pelvic fractures.

Neuromuscular Anatomy

The cauda equina travels through the sacral spinal canal and exits through the sacral neural foramina to form the lumbar and sacral plexus. Injury to the posterior bony pelvis and sacrum can result in neurologic deficits in the lower extremities and autonomic dysfunction involving the bowel, bladder, and genitalia.

Pathophysiology and Key Patterns of Pelvic Fracture

Numerous classification schemes for pelvic fractures have been created. Two widely used schemes for pelvic injury are presented here. The Tile classification stresses the biomechanical stability of the pelvic ring (Box 48.1). The Young-Burgess classification emphasizes the mechanisms of injury (Box 48.2). From a practical viewpoint, it is highly useful to consider both of these elements in the assessment of a pelvic ring fracture. Both classification systems delineate numerous subtypes of injuries, the interobserver reliability of which has been questioned. For the emergency clinician,
A good understanding of the principles of pelvic stability and the mechanism of injury is far more important than a detailed knowledge of injury subtypes. The broad distinction between mechanically stable and unstable fractures of the pelvic ring is clinically useful in assessing patients, because it has been demonstrated consistently that those with unstable injuries have a higher mortality rate and greater transfusion requirements.

Stable Injuries (Tile Type A)

Fractures of individual bones without involvement of the pelvic ring represent one-third of all pelvic fractures. Most stable pelvic fractures heal well with rest and analgesia (Fig. 48.4).

Undisplaced or Minimally Displaced Fractures of the Pelvic Ring. The normal pelvis is not totally rigid because of the slight mobility at the sacroiliac joints and symphysis pubis and the inherent elasticity of bone. It is possible to sustain a single break in the ring but the pelvis is not totally forgiving, so identification of a single break in the ring should prompt a thorough search for a second disruption.

The most common pelvic ring fracture is an isolated fracture of the superior or inferior pubic ramus. These fractures are stable.
Fractures of the superior and inferior pubic rami on the same side is a commonly encountered injury after a fall or MVC. These are generally stable fractures and are treated conservatively. However, the presence of significant displacement at the fracture site indicates a second disruption elsewhere in the pelvic ring. Alternatively, fractures of both rami on the same side can be associated with an unrecognized impaction fracture of the posterior pelvis.

If the patient with a ramus fracture reports posterior pelvic pain and if plain radiographs do not reveal a posterior injury, further investigations could reveal posterior fractures, such as occult bony or ligamentous injury of the acetabulum or sacroiliac joint. Up to 95% of elderly patients with isolated ramus fractures on plain films will have a sacral fracture detected by magnetic resonance imaging (MRI). This finding does not alter treatment, however, and an MRI is not indicated for most elderly patients with ramus fractures. Among the mechanically stable pelvic fractures, the lateral compression type I fracture described by Young and Burgess (Fig. 48.5), characterized by a pubic ramus fracture with ipsilateral sacral compression, bears special consid-eration. This fracture has a mortality rate of nearly 10% and a high incidence of associated injuries.

A straddle fracture is a four-pillar injury involving fractures of both pubic rami on both sides of the symphysis pubis, creating a “butterfly segment” (Fig. 48.6) and is produced by a direct blow with a straddle mechanism. Although these fractures can occur without posterior arch disruption, four-pillar injuries are commonly associated with lateral compression or vertical shear forces, which can cause concomitant injuries to the posterior pelvic arch. Computed tomography (CT) of the pelvis is required in four-pillar injuries to precisely detect and classify the posterior arch injury and to plan orthopedic treatment. The genitourinary tract is often injured with this type of pelvic fracture and should be evaluated carefully (see Fig. 48.6).

An isolated fracture of the iliac wing was first described by Duverney in 1751 and now bears his name. It is caused by direct trauma to the iliac crest, usually by lateral compression forces. Although there is usually minimal displacement because of the arrangement of the muscle attachments of the abdominal wall, orthopedic consultation is recommended. Extension of the fracture into the acetabulum alters treatment and prognosis. Severely displaced fractures of the iliac wing require open reduction and internal fixation (ORIF). A high incidence of major associated non-pelvic injuries has been reported among patients with isolated iliac wing fracture.

**Transverse Fractures of the Sacrum.** Transverse fractures of the sacrum do not compromise the pelvic ring. Transverse fractures at or below the S4 level are unlikely to be accompanied by neurologic injury. An upper sacral transverse fracture is the result of a flexion injury, such as being struck on the lower back by a heavy load while bending over, or by direct forces to the sacrum, as in a fall from a great height. The patient often reports pain in the buttocks, perirectal area, and posterior thighs. There may be local pain, swelling, and bruising overlying the sacrum. Gentle bimanual rectal examination might elicit severe pain and abnormal motion and allow detection of a palpable hematoma. Radiographically, the fracture may be difficult to visualize on anteroposterior and lateral projections, in which case a pelvic outlet view may be helpful. Simple transverse fractures at or below

---

**BOX 48.1**

**Tile’s Classification of Pelvic Fractures**

Type A: Stable, posterior arch intact; includes avulsion fractures, isolated iliac wing fracture, pubic ramus fractures, minimally displaced ring fracture, and transverse fractures of the sacrum or coccyx.

Type B: Partially stable, incomplete disruption of the posterior arch; includes anteroposterior injuries (“open-book” fracture) and lateral compression injuries; may be unilateral or bilateral; these injuries are rotationally unstable but vertically stable.

Type C: Unstable, complete disruption of the posterior arch; includes iliac, sacroiliac, and vertical sacral injuries that result from vertical shearing forces; may be unilateral or bilateral. These injuries are both rotationally and vertically unstable.

---

**BOX 48.2**

**Young-Burgess Classification of Pelvic Fractures**

**ANTEROPOSTERIOR COMPRESSION**

I. Symphyseal diastasis < 2.5 cm
II. Symphyseal diastasis ≥ 2.5 cm, sacrospinous and anterior sacroiliac ligament disruption, results in rotational instability
III. Symphyseal diastasis ≥ 2.5 cm, with complete disruption of the anterior and posterior sacroiliac ligament, results in complete rotational and vertical instability

**LATERAL COMPRESSION**

I. Sacral crush injury on ipsilateral side
II. Sacral crush injury with disruption of posterior sacroiliac ligaments; iliac wing fracture may be present (crecent fracture); rotationally unstable
III. Severe internal rotation of ipsilateral hemipelvis with external rotation of contralateral side (“windswept” pelvis), rotationally unstable

**VERTICAL SHEAR**

Vertical displacement of symphysis and sacroiliac joints resulting in complete rotational and vertical instability

**COMBINED MECHANISMS**

Any combination of the aforementioned mechanisms

---

**Fig. 48.4.** Fractures of individual pelvic bones. 1, Avulsion of anterosuperior iliac spine; 2, avulsion of anteroinferior iliac spine; 3, avulsion of ischial tuberosity; 4, fracture of superior pubic ramus; 5, fracture of inferior pubic ramus; 6, fracture of ischial ramus; 7, fracture of iliac wing; 8, transverse fracture of sacrum; 9, fracture of coccyx. (From Tile M: Fractures of the pelvis and acetabulum, ed 3, Philadelphia, 2003, Lippincott, Williams & Wilkins.)
S4 are treated conservatively. Above S4, neurologic injuries are common, necessitating careful clinical evaluation and surgery when neurologic compromise is present.

Avulsion Fractures. These usually occur during athletic activities and are the result of a sudden, forceful muscular contraction or excessive muscle stretch. They are seen more commonly in older children and teenagers before the corresponding physis closes; adults can have the same symptoms from ligamentous injury at these sites, which would not be evident on a plain film or CT scan. The sites of ligamentous attachments on the pelvis are highlighted in Figure 48.7.8

The ischial tuberosity can be avulsed during strenuous contraction of the hamstrings. The result is pain on palpation of the involved tuberosity, which is increased by flexion of the hip with the knee in extension (hamstrings stretched), but not with the knee flexed (hamstrings relaxed). Ischial tuberosity avulsion can also cause chronic discomfort without a history of acute injury.

A portion of the iliac crest epiphysis can be avulsed by contraction of the abdominal muscles. Similarly, the anterior superior iliac spine can be avulsed by forcible contraction of the sartorius muscle. Forceful contraction of the rectus femoris (as in kicking a ball) can result in the less common injury of anterior inferior iliac spine avulsion; however, this radiographic finding should be distinguished from a normal variant, the os acetabuli, which is a secondary center of ossification at the superolateral margin of the acetabulum.7 The physical examination is similar in these injuries and reveals local pain, swelling, and limitation in the motion of the hip.

Conservative treatment, including analgesia and bed rest in a position that avoids tension on the affected muscles, is generally all that is required for avulsion injuries; surgical treatment is rarely necessary. Orthopedic consultation is advised for follow-up care.

Stress Fractures. Stress fractures can occur with vigorous athletic or military training and in the last trimester of pregnancy. The diagnosis of stress fractures is based on the clinical evaluation and can be confirmed, if required, by radionuclide bone scan, although MRI has been shown to be a superior method for detecting these injuries.8

Pathologic and Insufficiency Fractures. Pathologic fracture related to neoplasm, Paget’s disease, or dietary osteomalacia should be included in the differential diagnosis of any pelvic fracture. Radiation therapy increases the risk of pelvic fracture.
CHAPTER 48 Pelvic Trauma

Symphysis widening of less than 2.5 cm is considered a stable injury (the symphysis is normally ≤0.5 cm in an adult but can increase 2 to 3 mm during or after pregnancy); however, with continued force in the anteroposterior direction, the hemipelvis externally rotates, tearing the sacrospinous, sacrotuberous, and anterior sacroiliac ligaments. The sacroiliac joint opens and hinges on the intact posterior sacroiliac ligaments. The resulting injury is aptly described as an "open-book" fracture. The pelvis is rotationally unstable in the horizontal plane, but the intact posterior sacroiliac ligaments maintain vertical stability.

When diastasis of the pubic symphysis is greater than 2.5 cm on an anteroposterior radiograph, the posterior injury is usually seen as widening of the sacroiliac joint and occasionally as a sacral or iliac fracture (see Fig. 48.5). If the injurious forces continue,
they can separate the hemipelvis, and the sacroiliac joint is seen as widely separated on a plain anteroposterior radiograph (Fig. 48.8) and on CT. The anteroposterior radiograph can be misleading in suggesting a pure open-book fracture in cases with symphysis disruptions greater than 2.5 cm. These cases commonly are associated with vertical shear fractures, so careful clinical and CT assessment for vertical instability is essential to classify the fracture properly and plan treatment accordingly.

These same forces can also injure the neurologic and vascular structures at the posterior arch; the overall volume of the pelvis is increased in the open-book injury, facilitating the expansion of a retroperitoneal hematoma. Several studies have demonstrated that patients with severe grades of anteroposterior compression injuries have the highest crystalloid and blood requirements. In addition, these injuries can be associated with non-pelvic injuries that contribute to significant blood loss.

**Lateral Compression.** Lateral compression of the pelvic ring results in varying degrees of internal rotation of the affected hemipelvis. Initially, this causes buckling of the sacrum and horizontal pubic rami fractures. Rami fractures can occur on the ipsilateral or contralateral side, the latter being referred to as a “bucket-handle” fracture (Fig. 48.9).

As the magnitude of force increases, the symphysis can be disrupted, causing overlapping of the pubic bones. On plain radiographs, evidence of injury to the sacrum might be subtle; overlapping pubic bones with any significant displacement should prompt a search for a posterior injury.

Similar to the anteroposterior injury, as disruption of the posterior ligaments increases, so does rotational instability. In the most severe lateral compression trauma, the ipsilateral pelvis rotates internally to such a degree that the contralateral pelvis might externally rotate. This is referred to as a “windswept” pelvis. Lateral compressive injuries result in varying degrees of horizontal rotational instability; however, the vertical stability of the pelvis is maintained (see Fig. 48.9).

Because internal rotation causes the pelvic volume to decrease, lateral compressive injuries are generally associated with lesser degrees of blood loss than are anteroposterior injuries.

**Vertical Shear.** Vertical shear injuries are the most unstable injuries affecting the pelvic ring and are associated with violent axial loading of the hemipelvis (e.g., a fall from a height or “submarining” under a dashboard) that causes fractures in vertical planes. Anteriorly, the symphysis and rami could be disrupted. Posteriorly, gross displacement and instability in the rotational and vertical planes may be present through the sacrum, the sacroiliac joint, or the ilium such that the hemipelvis is displaced posteriorly and cephalad (see Fig. 48.10).

Avulsion of the ischial spine, the lower lateral lip of the sacrum, and the transverse process of the fifth lumbar vertebra (sites of insertion of ligaments) (Fig. 48.10 and Box 48.3) are important clues to the presence of vertical shear fractures. The vertical shearing forces transmitted through the bony pelvis are also transmitted through the rich vascular network and nerve plexus directly adjacent to the bone. This accounts for the major hemorrhage and neurologic injuries associated with vertical shear fractures.

**Vertical Sacral Fractures.** A crucial distinction in considering sacral fractures is that transverse fractures do not involve the pelvic ring, but vertical fractures do. Vertical sacral fractures are caused by high-energy injuries and were classified by Denis into three groups according to whether the fracture line extends (1)
These injuries carry a high risk of neurologic complications: 6% when lateral to the foramina, 28% when through the foramina, and 58% when medial to the foramina. Neurologic dysfunction correlates to the nerve roots involved but can also manifest as bowel, bladder, or sexual dysfunction. Surgery is commonly performed for fractures associated with neurologic dysfunction, with the goals of bony fixation of the sacrum and decompression of the affected nerve roots.

Open Pelvic Fractures

An open pelvic fracture is present when there is direct communication between the fracture site and a skin, rectal, or vaginal wound. These are potentially lethal injuries, especially if not recognized early; hemorrhage accounts for early mortality, and infection, sepsis, acute respiratory distress syndrome, and multiple system organ failure are causes of delayed death. The majority of older case series reported mortality rates greater than 50%; rates reported from more recent studies are generally less than 30%. A 2015 study of more than 30,000 patients reported in-hospital mortality of 2.7%, but this rate doubled for patients ages 55 to 70.
Fig. 48.10. A and B, Vertical shear fractures bilaterally. At first glance the pelvis appears normal because of the smooth, uninterrupted arcuate line, but careful interpretation reveals the extremely critical nature of the injuries. 1, Fractures through the sacrum—note loss of definition and symmetry of sacral foramina, indicating vertical fractures through both sides of the sacrum (see computed tomography [CT] scan in D). 2, Transverse process fragment from right L5 (iliolumbar ligament attachment) is pathognomonic for a vertical shear fracture through the right sacrum. 3, Transverse process fragment from left L5, pathognomonic for a vertical shear fracture through the left sacrum. 4, Both hemipelvises are dislocated cephalad because of the double-ring fractures through each side of the sacrum. This dislocation explains why the L5 transverse processes appear so close to the iliac crests. (The body of L5 is obscured because of rotational dislocation of the central free sacral fragment posteriorly and because of technique.) 5, Normal sacroiliac joints. C and D, CT scan of same pelvis. 1, Bilateral comminuted fractures of sacrum with lateral displacement of both hemipelvises; 2, normal sacroiliac joints.

Fig. 48.11. The Denis classification of vertical sacral fracture. Zone I is lateral to the sacral foramina (known as the sacral ala). Zone II is transforaminal. Zone III is the central sacrum medial to the foramina.
years old and quadrupled for patients older than 70 years old. Other predictors of mortality included injury severity, mental status, prolonged mechanical ventilation, or need for blood product administration.

The skin over the posterior pelvis and gluteal area and perineum must be inspected carefully for wounds. Some fractures are open only by virtue of a bone spicule penetrating the vagina or rectum, which can be identified by careful digital rectal examination (DRE) and vaginal examination. Hemorrhage from a large open laceration should be treated with direct manual pressure or pressure dressing. Traditionally, pelvic fractures communicating with the rectum have mandated a diverting colostomy; however, a systematic review of the literature on this topic found no difference in infection rates between patients treated with or without colostomy.

Penetrating Pelvic Trauma

Because of the complex anatomy of the viscera, blood vessels, and nerves within the pelvis, penetrating trauma to this area presents a major diagnostic challenge. Overall mortality in this group of patients is about 10%, but the mortality rate of patients who present in shock is as high as 50%. Vascular injuries can involve the aorta; common iliac artery; and external, internal, and common iliac veins or a combination of vessels. Genitourinary structures and hollow viscera could be injured; fecal contamination from colorectal injury is a serious complication. The finding of blood on DRE is an important clue that a rectal injury has occurred. Emergent surgical consultation is recommended for all cases of penetrating pelvic trauma.

Associated Pelvic Injuries

Urologic Injury

The overall incidence of bladder or urethral disruption associated with any pelvic fracture is approximately 5%, with increased risk among those with severe pelvic injuries. Because the urethra is far less exposed in women than in men, injury to the urethra in women with pelvic fracture is rare.

Patients with fractures of the anterior arch of the pelvis were at greatest risk for bladder injury. Diastasis of the symphysis more than 1 cm and fracture around the obturator ring with displacement more than 1 cm are associated with a tenfold and threefold increased risk for bladder rupture, respectively.

The presence of gross hematuria indicates injury of the lower urinary tract. Bladder rupture is diagnosed in about 25% of patients with gross hematuria and pelvic fracture. Patients with blood at the urethral meatus in the context of pelvic fracture have an incidence of up to 90% of urethral injury, and indicate the need for a retrograde urethrogram followed by a cystogram (see Chapter 40). Gross hematuria is variably investigated with a combination of urethrography, intravenous pyelography, cystography, and CT. The sequence and types of examinations are individualized for each patient. Fracture of the inferomedial pubic ramus and widened symphysis diastasis have both been shown to be predictive of a urethral injury. Retrograde urethrocystography done before CT of the pelvis might impair the ability of CT to detect extravasation of contrast, which would indicate active pelvic bleeding. Therefore, if CT is to be performed, it ideally is performed before retrograde urethrography.

Sexual dysfunction is a recognized complication of pelvic trauma, occurring in 44% of females and 50% of males. Even in the absence of a urethral injury, sexual dysfunction in men can occur secondary to neurovascular disruption associated with the pelvic fracture.

Neurologic Injury

The risk of neurologic injury correlates with instability of the pelvic injury, with a reported incidence of neurologic dysfunction of 2%, 4%, and 14% in Tile type A, B, and C fractures, respectively. Up to 10% of patients with acetabular fractures experience neurologic dysfunction. Neurologic injury occurs commonly in patients with vertical sacral fractures or transverse fractures above the S4 level. Up to 30% of patients with vertical fractures that involve the foramina have associated neurologic deficits. In patients with fractures medial to the foramina involving the spinal canal, almost two-thirds have neurologic deficits.

Pelvic injury can cause various plexopathies and radiculopathies, depending on the nerve root level at which the injury occurs (Table 48.1). In patients with sacral fractures, cauda equina syndrome may be fully or partially present. Hyperesthesia and subsequent anesthesia occur in a saddle-shaped distribution in the groin, as well as weakness of ankle plantar flexion, hamstrings, and gluteus muscles and decreased or absent ankle jerk. If the lower sacral roots are affected, the patient might experience neurogenic bladder with overflow incontinence, motor and sensory deficits in the lower extremities, anal sphincter dysfunction, or sexual dysfunction. Patients with neurologic deficits from sacral fractures require orthopedic or neurosurgical consultation.

Gynecologic Injury

Blood at the introitus may indicate a urethral injury, open pelvic fracture, or local laceration without communication with the bony pelvis. Delayed urologic or sexual dysfunction and complications with pregnancy are common after pelvic injury. Gynecologic consultation is recommended for any female who sustains an injury to the reproductive tract in association with a pelvic fracture and for all pregnant women who sustain a pelvic fracture of any kind.

Associated Non-Pelvic Injuries

The magnitude of force required to disrupt the pelvis commonly results in severe injuries to other organ systems. Among those patients who die as a result of pelvic fracture, it is rare that the fracture is an isolated injury. Associated injuries in trauma patients with pelvic fracture can contribute more to the mortality risk than the pelvic injury itself.

Although patterns of non-pelvic injuries associated with certain patterns of pelvic fracture have been described, these findings have not been reproduced consistently in the literature. Severe injuries to the head, spine, thorax, aorta, and abdomen can occur in patients with both stable and unstable pelvic fractures.

**Acetabular Fractures**

Pain and inability to bear weight are the hallmark complaints associated with acetabular fractures. On clinical examination, pain in the hip area with percussion of the heel of the foot or with medial pressure applied to the greater trochanter may indicate the presence of an acetabular fracture. The sciatic nerve is commonly injured suggested by the presence of a neurologic injury. A common mechanism of acetabular injury is the so-called “dashboard injury,” caused by the knee striking the dashboard during sudden deceleration, driving the head of the femur into the acetabulum. As a result, concurrent fracture or dislocation of the patella (or both) are common.

Acetabular fractures are broadly classified into three types (Fig. 48.12 and Box 48.4).

- **Type A** fractures are subdivided into anterior and posterior column injuries. Posterior wall fractures are the most common acetabular injuries and are generally caused by a forceful impact to a flexed knee (eg, dashboard injury)—the force is transmitted up through the femur through the posterior acetabulum. An associated posterior dislocation of the hip is frequently associated with posterior rim fracture of the acetabulum, which may result in an unstable hip joint, leading to recurrent dislocation. Posterior hip dislocation is commonly associated with secondary sciatic nerve injury. The anterior column of the acetabulum is commonly injured when a superior ramus fracture extends into the low anterior column.

- **Type B** fractures involve both anterior and posterior columns, but a portion of the acetabulum remains attached to the ilium and are associated with all major mechanisms of pelvic injury. Because of the forces involved, the diagnosis of a pelvic fracture should prompt a careful evaluation for other system injuries.

- **Type C** fractures are two-column fractures of the acetabulum, with none of the articular surface remaining attached to the axial skeleton. These fractures are readily apparent on plain radiographs as a result of disruption of the ilium.

When the columns are split, the injury is referred to as a *transverse (T-type) fracture*. The T-type fracture is associated with the worst prognosis, due to the difficulty in obtaining open anatomic reduction.

Type C fractures are two-column fractures of the acetabulum, with none of the articular surface remaining attached to the axial skeleton. These fractures are readily apparent on plain radiographs as a result of disruption of the ilium.

Assessment of an anteroposterior pelvic radiograph should focus on disruption of the ilioischial and iliopectineal lines, as well as the anterior and posterior lips of the acetabulum (Fig. 48.13). Ramus fractures should be evaluated for possible extension into the acetabulum. When plain films are used, oblique views of the acetabulum (Judet views) can aid in visualizing the anterior and posterior columns. CT is the imaging test of choice for visualizing acetabular fractures and, when deemed necessary, planning surgical repair. Because a fracture of the acetabulum often results from a high-energy mechanism, patients with isolated acetabular fractures could have significant hemorrhage necessitating blood transfusion. Patients with acetabular fractures require orthopedic consultation in the emergency department.

(Redrawn from Rogers LF, Novy SB, Harris NF: Occult central fractures of the acetabulum. Am J Roentgenol 124:98, 1975.)
Coccyx Fractures

Fractures of the coccyx are caused by a fall into the sitting position or being kicked in that area of the body. The bone can also be fractured during the birthing process. Physical examination reveals local tenderness to palpation in the gluteal crease cephalad to the anus. DRE may elicit pain and allow detection of abnormal motion of the coccyx. Normally, the tip of the coccyx moves 30 degrees anteriorly and 1 cm laterally. If displacement is detected during rectal examination, attempts at reduction are not recommended.

Radiographic confirmation of a coccygeal fracture is generally not necessary. Displaced fractures often are seen on the lateral view, but the diagnosis is evident on physical examination. Non-displaced fractures can be difficult to identify radiographically. Rarely does the knowledge gleaned from radiographic studies alter the therapy to a degree that warrants radiation exposure to the pelvis, especially in women.

Treatment of coccygeal fracture consists of limited activity (activity limited by pain), stool softeners, non-opioid analgesia, and hot baths, if they are symptomatically helpful. As activity is increased, maneuvers that minimize discomfort include the use of an inflatable rubber donut cushion while sitting, alternately sitting on the side of each buttock, slouching to displace body weight more proximally, and sitting on a hard chair rather than a soft one, as sinking into a soft chair distributes weight onto the coccyx. Because of ongoing muscle forces on the bony fragment, healing is slow, and patients should be told that discomfort will persist for 4 to 8 weeks. If severe disability persists, an orthopedic consultation is indicated for consideration of local steroid injection or possible coccyctomy. Coccydynia also can occur without fracture and is caused by trauma during parturition; faulty posture; midline disk herniation (caused by non-segmental referral of pain from irritation of the dura); lumbar facet arthropathy; compression of the first, fourth, and fifth sacral roots; neuralgia from sacral plexopathy or sacrococcygeal neuropathy; infections; and local tumors.

CLINICAL FEATURES

History

Understanding the mechanism of injury is an important means of determining a patient’s risk of having a pelvic fracture and, if present, its pattern and severity. Low-energy injuries (eg, ground-level falls) typically cause stable injuries to the pelvis; patients who have sustained high-energy injuries (eg, MVCs, falls from heights) are at risk for unstable fracture patterns of the pelvis, as well as associated injuries to other organ systems.

Determining the direction of forces applied to the pelvis can also give important clues to the types of injury sustained. Anteroposterior forces (eg, head-on MVCs) can cause open-book injuries to the pelvis. Lateral forces (eg, side-impact collisions) can disrupt the posterior ligaments; however, the pelvic floor generally remains intact. Vertical shear injuries (eg, falls from height) can disrupt the posterior ligaments and pelvic floor, causing gross instability of the pelvis.

Age is an important consideration in patients with pelvic fracture. When compared with their younger counterparts, elder patients have lower density bone, which fractures more easily, increased likelihood of hemorrhage, higher morbidity and mortality with pelvic fracture, greater comorbidity, and worse outcomes after acute resuscitation from hypotension.

Physical Examination

On inspection, rotation of the iliac crests indicates a serious pelvic fracture. Leg-length discrepancy suggests a hip injury or cephalad migration of an unstable hemipelvis. Careful inspection of the skin and skin folds is necessary to identify open fractures. Perineal or genital ecchymosis or hematoma might be observed, and if many hours have elapsed since the injury, ecchymosis in the periumbilical area (Cullen’s sign), in the flanks (Grey Turner’s sign), or over the inguinal ligament (Fox’s sign) from retroperitoneal hemorrhage could be present. Careful palpation of the pelvic ring, seeking the presence of point tenderness, is imperative; palpation starts at the symphysis anteriorly and proceeds to both pubic rami, the iliac spines and crests, and finally to the sacrum and sacroiliac joints posteriorly. The presence of tenderness in any of these locations is an important indicator of pelvic ring injury in alert patients without distracting injury.

Manipulation of the pelvis during physical examination is essential to help determine stability, but pressure should initially be applied gently and progressively increased, as long as the patient does not report pain. “Spring boarding” (ie, vigorous downward pressure on the anterior superior iliac spines) to assess the rotational stability of the pelvic ring should be strictly avoided, because this maneuver has the potential to disrupt any tenuous blood clotting that may have occurred around a fracture site and can therefore worsen hemorrhage. Inward stability should be checked by bilateral compression of the iliac wings before outward stability to minimize the risk of opening the pelvis and causing more internal bleeding.

The penis should be milked to examine for blood at the meatus. DRE, once a fixture in assessment of pelvic trauma, is not sufficiently sensitive or specific to guide diagnosis of urethral or bladder injury (see Chapter 40). The DRE allows evaluation of sensation and sphincter tone for spinal cord injury, and the presence of frank blood, indicating possible mucosal disruption. A vaginal speculum examination should be performed to assess for an open fracture in women identified with fracture on imaging. If operative intervention is planned, this examination, which can be uncomfortable and distressing, is deferred to the operating room. Because it is possible to create an open fracture iatrogenically through the vaginal or rectal wall, the DRE and vaginal examination must be performed carefully, especially in unconscious patients who cannot localize pain. The examiner should be mindful when performing these examinations that bony spicules can lacerate the examining finger. Extravasated urine might be detected in the scrotum or the subcutaneous tissues of the penis, vulva, or abdominal wall. The presence and quality of pulses in the lower limb should be assessed, as should sensation, strength, and deep tendon reflexes.

DIFFERENTIAL DIAGNOSIS

Pain can be referred from a multitude of areas. A detailed history and physical examination will often elicit the cause of a patient’s pain. The causes of pelvic pain after trauma are outlined in Table 48.2. Thorough examinations of the back, abdomen, and lower extremities are necessary to exclude referred pain and associated injuries.

DIAGNOSTIC TESTING

Radiology

Plain Radiography

Routine radiographs of the pelvis are not necessary after blunt trauma if the patient is asymptomatic, awake, and alert and has normal findings on physical examination of the pelvis, including lack of tenderness to lateral and anteroposterior compression and to direct pressure applied to the symphysis pubis. However, routine anteroposterior plain radiography is indicated for patients...
with severe mechanisms of injury, such as MVC, pedestrian struck by motor vehicle, or fall greater than 10 feet, who are symptomatic or whose examination is compromised by either a decreased level of consciousness or distracting injuries.

On the anteroposterior radiograph, the symphysis pubis is normally no more than 0.5 cm wide, and a small (1- or 2-mm) vertical offset of the left and right pubic rami is normal. Overlapping at the symphysis pubis is abnormal and is the result of a severe crushing injury. Normally the sacroiliac joint is approximately 2 to 4 mm wide.

On the anteroposterior view, the degree of pelvic rotation caused by technique and positioning can be judged by the presence of asymmetry in the size and shape of the left and right obturator foramina and iliac wings. Diastasis of the sacroiliac joint also causes an asymmetric appearance of the obturator foramina and the iliac wings. If there is displacement into external rotation, the affected iliac wing appears broader and the anterior iliac spine appears more prominent. Avulsion fracture of the fifth lumbar transverse process by the iliolumbar ligament often accompanies an sacroiliac joint disruption or a vertical sacral fracture and is a valuable clue to posterior arch injuries (see Fig. 48.10 and Box 48.3). Several studies have shown that plain pelvic radiography has insufficient sensitivity and specificity to definitively identify or exclude pelvic fractures, and plain radiography is not generally necessary when abdominopelvic CT evaluation is planned. In particular, sacral fractures and sacroiliac joint disruptions are not well visualized on the anteroposterior view. However, the addition of inlet and outlet views of the pelvis increases the sensitivity and specificity of plain radiographs in detecting significant pelvic fracture (Fig. 48.14) and sacroiliac joint disruption and should be considered in all patients with presumed stable anterior pelvic ring injuries with any complaints of posterior pelvic pain for whom CT scanning is not anticipated.

When patients are too unstable to undergo CT investigation, or when significant hemorrhagic shock is present in the context of clinically suspected pelvic fracture, the anteroposterior pelvic radiograph is useful to screen for the pelvic injuries that are most often associated with major blood loss and that might require urgent intervention. Findings that predict the need for transfusion include an open-book fracture or displacement of 0.5 cm or more at any fracture site in the pelvic ring in combination with a displaced symphysis pubis, a displaced obturator ring fracture, or obvious vertical displacement in the posterior pelvis. Any of these signs could be associated with posterior pelvic injury. Therefore, plain radiography can be a vital test for patients who are unstable, those who are suspected to have unstable pelvic fracture on clinical examination, or those for whom CT cannot be immediately performed and may alert the clinician of the need for surgery, angiography, or other definitive management of pelvic hemorrhage.

Computed Tomography

CT is the imaging test of choice for evaluating the injured pelvis. CT provides detailed information about the posterior arch and rotational deformities that indicate the relative stability of the pelvic ring; furthermore, the acetabulum, which can be difficult to assess with plain radiographs, is well visualized with CT. Furthermore, abdominopelvic CT provides detailed information about concomitant injury to abdominal organs, which aids in the planning of laparotomy, external fixation of the pelvis, angiography, and definitive orthopedic management. Controversy exists regarding whether all high risk patients should undergo “pan-scan,” which is CT scanning of the head, neck, chest, abdomen, and pelvis, or whether a selective approach is better, using clinical indications to guide CT scanning. Proponents of pan-scanning argue that selective scanning of high-energy trauma patients leads to a high miss rate for important diagnoses that alter treatment plans. However, although selective CT scanning misses some injuries, fewer than 5% of those missed injuries require a change in the treatment plan. Scan ordering should be based on the evaluation of the patient in the resuscitation bay, accounting for mechanism of injury, hemodynamic status, and suspicion of injury on physical examination. Some patients will require a pan-scan, but doing this amount of imaging on all patients meeting certain global criteria results in unnecessary radiation exposure, resource use, and expense. In general, CT scanning protocols are based on institutional preferences, somewhat guided by the literature. Imaging of the multiple-trauma patient is discussed in Chapter 33.

Unless a patient requires an immediate lifesaving surgical intervention, it is recommended that CT be used to evaluate all patients with high-energy mechanisms of injury if pelvic fracture is suspected or has been confirmed by plain radiography; this will help delineate the injury.

Evaluation of Hemorrhage

Hemorrhage is the most devastating direct complication of pelvic fracture. In the original series of high-energy pelvic injuries used to formulate their classification system, Burgess and colleagues found that an average of 14.8 units of blood were transfused in the anteroposterior compression group, 9.2 units in the vertical shear group, and 3.6 units in the lateral compression group. The correlation between transfusion requirements and type of pelvic fracture has been confirmed in other studies that demonstrate that unstable fracture patterns increase the need for transfusion and risk of mortality.

Major pelvic hemorrhage results from lacerations of the rich vascular network supplying the pelvis in the retroperitoneal space. Pelvic hemorrhage is commonly venous in origin; an intact peritoneum may help contain or tamponade a retroperitoneal hematoma. However, it is possible for bleeding to extend beyond the retroperitoneum and disect into the anterior abdominal wall or through the peritoneum into the abdominal cavity. Bleeding can also occur from the marrow at the fracture sites. Finally, coagulopathy can lead to persistent retroperitoneal bleeding and should be considered when the patient does not respond to fluid and blood replacement.

The combination of pelvic and intra-abdominal bleeding is associated with devastating outcomes. Major pelvic injury is
because a negative abdominal exploration is associated with a higher mortality rate for hemodynamically unstable patients with pelvic fractures.

**Diagnostic Peritoneal Lavage**

DPL, once widely accepted as an accurate means of establishing the presence of intra-abdominal hemorrhage, has been largely associated with intra-abdominal injuries in up to one-third of cases, particularly the liver and spleen. In the patient with pelvic fracture who is in shock, it is important to establish early whether hemorrhage is occurring within the abdominal cavity and thus necessitating laparotomy. Diagnostic strategies for evaluation of hemorrhage resulting from pelvic fracture include diagnostic peritoneal lavage (DPL), ultrasound, and CT. Regardless of which is chosen, unnecessary laparotomy should be avoided at all costs.
supplanted by ultrasound and CT scanning. When DPL is used, a supra-umbilical peritoneal aspirate that is negative for blood indicates that the peritoneal cavity is not a major source of bleeding or a significant contributor to hemorrhagic shock. In the absence of another identified source of blood loss, a negative peritoneal aspirate in a patient with a major pelvic fracture and hypotension indicates pelvic hemorrhage. Gross aspiration of blood suggests major intra-abdominal hemorrhage, and pelvic stabilization, as indicated, with urgent laparotomy is recommended for hemodynamically unstable patients.

Ultrasound

Focused assessment with sonography in trauma (FAST) is the standard approach used to identify free intraperitoneal fluid in the trauma patient. An important caveat is that FAST is not helpful for evaluating the retroperitoneal space, where pelvic hemorrhage commonly occurs, but FAST has essentially completely replaced DPL to identify whether intraperitoneal bleeding is the cause of the hypotension, leaving the pelvis as the culprit when FAST is negative. Although a positive FAST study is widely used to decide whether to perform laparotomy in a hemodynamically unstable patient, its reliability in patients with major pelvic injury has been questioned. Sensitivity is about 80% and specificity 95% for the detection of hemoperitoneum in patients with pelvic fracture. The use of FAST in the evaluation of blunt abdominal trauma is discussed in Chapter 39.

Computed Tomography

CT is the diagnostic test of choice for detecting pelvic and intra-abdominal injuries. It reveals bleeding in the peritoneal and the retroperitoneal spaces. In many cases, CT with intravenous contrast can distinguish a stable hematoma from ongoing bleeding from pelvic arteries. The presence or absence of extravasated intravenous contrast material on CT of the pelvis is useful in predicting which patients will require therapeutic angiography. However, absence of extravasation does not exclude the possibility of ongoing pelvic bleeding. Pelvic computed tomography angiography (CTA) can localize active pelvic bleeding and also distinguish bleeding from arterial and venous sources. This distinction can have great impact on the decision to perform therapeutic angiography for active arterial bleeding.

MANAGEMENT

Resuscitation

Blunt trauma patients who have the combination of pelvic ring fractures and hemorrhagic shock have a mortality rate of approaching 50% and may require massive quantities of blood products. For patients in shock, resuscitation is as described in Chapter 33.

For patients with pelvic fracture, achieving a normal pulse and blood pressure with fluid resuscitation alone in the ED may be an unrealistic goal. Such attempts may contribute to ongoing bleeding and may delay definitive treatment that can halt the hemorrhagic process.

Intravenous access in the lower limbs should be avoided in patients with severe pelvic fractures, because infused fluids and blood products might be lost through venous bleeding into the retroperitoneal space.

Box 48.5 details methods for controlling hemorrhage during the ED management of patients with pelvic fractures.

BOX 48.5

Pelvic Fracture–Related Hemorrhage: Goals in the Emergency Department

1. Resuscitation: Recognize the patient who is in hemorrhagic shock and initiate blood transfusion early in the resuscitation.
2. Recognition: Realize that patients with posterior arch injuries are at higher risk for pelvic hemorrhage.
3. Evaluation: Identify associated non-pelvic injuries (especially head, chest, and intra-abdominal) that contribute immensely to an increase in mortality in patients with pelvic fracture.
4. Stabilization: Wrapping the pelvis in a sheet and towel clamps is the easiest way to immobilize the pelvis in the emergency department. Stabilization by external fixation or pelvic C-clamp should be performed by orthopedic surgeons.
5. Control of pelvic bleeding: Angiography is highly effective in treating pelvic arterial hemorrhage. Pelvic packing during laparotomy is another way of controlling bleeding. Institutional practices determine if one or both techniques are used.

Control of Hemorrhage

In addition to blood transfusion, two important therapeutic modalities for control of hemorrhage are mechanical stabilization of the pelvis and angiographic embolization. There has been some debate as to which of these modalities should take precedence, and this has been predicated on institutional availability. As a general rule, angiography with therapeutic embolization of bleeding arteries is more effective than and takes precedence over invasive external fixation.

Stabilizing the Pelvis

Noninvasive Techniques. The most readily available means to stabilize the pelvis quickly in the ED is a sheet and towel clamps. Wrapping the pelvis tightly with a sheet and securing it with towel clamps can reduce an open-book pelvic injury (Fig. 48.15) and the potential volume in the pelvis for blood loss.

Other commercial circumferential compression devices have been developed to facilitate noninvasive stabilization of the pelvis. Cadaveric studies suggest that these devices are effective at reducing an open-book pelvis. Patients with exsanguinating pelvic hemorrhage treated with a noninvasive splinting device appear to fare as well as those for whom formal external fixation was performed emergently.

Patients with open-book pelvic injuries are most likely to derive benefit from tight wrapping of the pelvis. This maneuver might not be desirable when lateral compression forces have already internally rotated the hemipelvis—indiscriminately forceful wrapping could, in fact, worsen the degree of displacement. Therefore, some judgment is required to discern whether one is wrapping the pelvis to reduce the volume of an externally rotated pelvis or splinting a pelvis to minimize movement, especially when the patient is repositioned.

Formal External Fixation. External fixation of the pelvis is performed by orthopedic surgeons to prevent movement at fracture sites and to control attendant bleeding. Application of an external fixator does not appear to decrease morbidity or mortality rates but may improve clinical outcome by limiting hemorrhage and restoring mechanical integrity. Application of a fixator is a time-consuming process; it should not be attempted if it will delay more definitive treatment of pelvic bleeding by angiography or the treatment of other sources of severe blood loss. The timing
of the application of the external fixator requires coordination among the emergency medicine trauma captain, trauma surgeon, orthopedic surgeon, and interventional radiologist. Early surgical consultation is needed for efficient planning and prioritization of surgical management.

Many stable anteroposterior and lateral compression fractures can be treated definitively with an external fixator. When the pelvis is vertically displaced, traction combined with external fixation is necessary to reduce the pelvis, pending definitive open surgical repair. Most fixators can be constructed to allow convenient surgical access to the abdomen and groin.

The specific mode of invasive fixation is specific to the institution and the orthopedic or trauma consultant.

Angiography and Embolization

Arteriography and venography have been evaluated for their utility in managing hemorrhage associated with pelvic fractures. Although pelvic bleeding is commonly venous in origin, venography is not useful in management; extensive anastomoses and valveless bidirectional collateral flow make embolization impractical. In contrast, arteriography is excellent at both diagnosing and managing arterial bleeding.

Angiography is indicated when hypovolemia persists in a patient with a major pelvic fracture despite control of hemorrhage by other means. Although it is impossible to determine whether bleeding is venous or arterial in origin until angiography is performed, an inadequate response to initial resuscitation (defined as failure to maintain a systolic blood pressure above 90 mm Hg after the administration of 2 or more units of packed red cells or less) and the presence of contrast extravasation on admission CT are indicative of active arterial bleeding. Although the presence of contrast extravasation on CT is an indication for angiography, the absence of contrast blush on CT is not sufficient to rule out serious pelvic bleeding. Sacroiliac joint disruption, persistent systolic blood pressure below 100 mm Hg, and female gender have been shown to be predictors of the need for embolization at the time of angiography.

The timing of angiography is individualized for each patient, depending on priorities for the treatment of concomitant injuries. Posterior arch disruptions are associated with the most severe hemorrhage; angiography should be considered at an early stage for patients with this injury. Whether patients undergo angiography immediately from the ED or immediately preceding laparotomy, it is important to be mindful of the logistical delay that often occurs in mobilizing the angiography team, so this intervention should be anticipated as early as possible. Transfer to the angiography suite requires orchestrating the necessary personnel and equipment to care for a critically injured patient. The use of mobile angiography equipment in the ED to control pelvic hemorrhage has been reported; this option removes the logistic delays while ensuring a greater degree of safety in monitoring patients during the procedure.

The contrast material for arteriography is injected through the femoral artery on the less-injured side or via the upper extremity. The examination starts above the level of the aortic bifurcation and proceeds to selective branches of the internal iliac (hypogastric) artery. Transcatheter embolization with thrombogenic coils, foam, or spherules is used to stop hemorrhage from the branches of the internal iliac artery.

Embolization is highly effective for controlling arterial bleeding, with fewer than 10% of patients requiring a repeat procedure because of ongoing bleeding. The complications that can result from embolization include gluteal muscle necrosis, surgical wound breakdown, infections, impotence, and bladder necrosis.

Hemodynamically Unstable Patients With Pelvic and Intra-Abdominal Hemorrhage

Patients who hemorrhage from both the pelvis and the abdomen have mortality rates above 40% and deserve special consideration. These patients may be too unstable to undergo CT imaging.
Prioritizing the need for laparotomy versus angiography in these patients becomes challenging when the need for laparotomy is based on the detection of intra-abdominal fluid by FAST (or DPL). Unnecessary laparotomy performed in patients who are hemodynamically unstable with pelvic fracture further exacerbates their high mortality rate. In these cases, it is crucial that the general or trauma surgeon, orthopedic surgeon, and interventional radiologist coordinate their efforts to optimize the timing of necessary procedures.

If DPL is performed, gross aspiration of blood is a strong indicator for prompt laparotomy. FAST examination is used similarly. A positive FAST examination indicates hemoperitoneum, and it is generally accepted that laparotomy should be pursued before angiography in such cases. Given the significant rate of false-negative FAST examinations in patients with pelvic trauma, a single negative FAST examination should not be considered to exclude significant intraperitoneal hemorrhage. However, patients with hemorrhagic shock and a negative FAST examination with adequate windows likely are bleeding from the pelvis injury. When concurrent pelvic bleeding is highly suspected (eg, in patients with severe open-book pelvis), it is advisable that angiography promptly accompanies Expert Consult website.

**KEY CONCEPTS**

- The most serious pelvic ring injuries caused by high-energy impact are 1) anteroposterior compression fractures (“open-book” fracture), 2) vertical shear fractures, and 3) fractures involving significant displacement. These injuries are associated with major blood loss and transfusion requirements.
- Pelvic injury is a marker for serious injury to other organ systems. The vast majority of patients who die after sustaining a pelvic fracture have multiple trauma.
- Careful examination of the perineum and buttocks, as well as digital rectal and vaginal examinations, are necessary to diagnose open fractures.
- Computed tomography (CT) is the imaging test of choice to diagnose pelvic fracture and concurrent intra-abdominal injuries for patients stable enough to undergo the scan. CT aids in establishing surgical priorities and planning of definitive orthopedic care. The significance of contrast extravasation during CT imaging is a subject of ongoing research regarding the ability to distinguish between arterial and venous sources of pelvic bleeding.
- In the hemodynamically unstable patient who cannot undergo CT imaging, the anteroposterior radiograph usually reveals serious pelvic fractures that cause major pelvic bleeding, which is sufficient information to undertake pelvic stabilization if indicated.
- The combination of posterior arch fracture plus hypotension is associated with a mortality rate of approximately 50%.
- Early fluid resuscitation with blood products is recommended for patients suspected of having active pelvic bleeding.
- Trauma hospitals should have institutional guidelines and mechanisms to facilitate early decisions regarding the treatment for pelvic hemorrhage. Treatment options include angiography and embolization, pelvic packing, invasive fixation, or any combination of these therapies.
- Unstable patients with a positive FAST and a pelvic fracture should be treated with laparotomy with pelvic stabilization and possible pelvic packing, and then angiography.
- Unstable patients with a negative FAST and a pelvic fracture should be treated with pelvic stabilization (eg, a pelvic binder) and angiography, and then a repeat FAST and laparatomy if they remain unstable.
- “Open-book” pelvic fractures should be internally compressed with a pelvic binder or sheet to reduce the size of the pelvis, unless the fracture forces have already internally rotated the hemi-pelvis as this could cause an increase in the pelvic diameter.

CHAPTER 48: QUESTIONS & ANSWERS

48.1. While examining a patient with blunt abdominal trauma, you note blood at the urethral meatus. What is the most appropriate next step in the patient's management?

A. Order a cystography
B. Order a retrograde urethrogram
C. Order a urinalysis
D. Order an anterograde urethrogram
E. Order an intravenous pyelography

Answer: B. Blood at the urethral meatus necessitates a retrograde urethrogram followed by a cystogram. Gross hematuria is investigated by a combination of urethrogramy, intravenous pyelography, cystography, and computed tomography (CT).

48.2. An avulsion fracture caused by the rectus femoris muscle most likely involves which of the following structures?

A. Anterior inferior iliac spine
B. Anterior superior iliac spine
C. Iliac crest
D. Ischial tuberosity
E. Sacrum

Answer: A. Forceful contraction of the rectus femoris (as in kicking a ball) can result in an injury of anterior inferior iliac spine avulsion. The ischial tuberosity may be avulsed during strenuous contraction of the hamstrings. A portion of the iliac crest epiphysis may be avulsed by contraction of the abdominal muscles. The anterior superior iliac spine may be avulsed by forcible contraction of the sartorius muscle.

48.3. A 25-year-old patient involved in a motor vehicle collision (MVC) presents with a suspected unstable pelvic fracture. Vital signs are: blood pressure, 90/50 mm Hg; heart rate, 120 beats per minute; and respiratory rate, 22 breaths per minute. What is the most appropriate next step in this patient's management?

A. Call trauma service for immediate laparotomy
B. Call orthopedics for fixation
C. Chest, abdominal, and pelvic radiographs
D. Computed tomography (CT) scan of the abdomen and pelvis
E. Perform serial abdominal and focused assessment with sonography in trauma (FAST) examinations
Answer: C. The addition of inlet and outlet views of the pelvis has been shown to increase the sensitivity and specificity of plain radiographs in detecting significant pelvic fracture. When patients are too unstable to undergo CT investigation, the anterior/posterior portable radiograph is useful in screening for pelvic injuries that are most associated with major blood loss. Findings with this technique that have been reported to predict the need for transfusion include “open-book” fracture or displacement of 0.5 cm or more at any fracture site in the pelvic ring, and displaced symphysis pubis or obturator ring fracture.

48.4. Which of the following treatments can provide definitive control of hemorrhage from severe pelvic fracture?
   A. Blood transfusion
   B. Commercial circumferential pelvic compression devices
   C. External fixation
   D. Transfusion of concentrated clotting factors
   E. Wrapping pelvis with sheet

Answer: C. External fixation is an invasive strategy aimed at cessation of pelvic hemorrhage. Options A and E are important for the emergency clinician to quickly stabilize a mechanically unstable pelvic fracture and hopefully minimize bleeding, but these options, per se, are not definitive treatments. Transfusion of blood products is important in overall resuscitation of the patient but does not stop bleeding from pelvic fractures.

48.5. Which of the following radiographic findings necessitates further evaluation of the pelvic ring?
   A. Asymmetry of the pelvis caused by rotation
   B. Duverney fracture
   C. Sacroiliac joint 4 mm wide on pelvic radiograph
   D. Symphysis pubis 7 mm wide
   E. Transverse fracture of the sacrum

Answer: D. On the anteroposterior radiograph, the symphysis pubis is normally no more than 5 mm wide, and a small (1 or 2 mm) vertical offset of the left and right pubic rami may be normal. Normally, the sacroiliac joint is approximately 2 to 4 mm wide. On the anteroposterior view, the physician may judge the degree of pelvic rotation caused by technique and positioning by the presence of asymmetry.
Fractures of the femur are notable for their associated morbidity and mortality. Women are at increased risk for both femoral neck fractures and intertrochanteric fractures. Femoral neck fractures have a female-to-male ratio of 4:1 and typically occur in elderly patients with osteoporosis. The incidence of intertrochanteric fractures increases with age, and women are affected six times more often than men.\(^1\) More than three-quarters of all hip fractures occur in postmenopausal women older than 50 years old.

In the emergency care setting, nontraumatic hip pathology is also very common among the elderly segment of society. Osteoarthritis of the hip can severely limit one's ability to perform activities of daily living.

The elderly are not the only population affected by hip and femur pathology. Perthes' disease, or avascular necrosis (AVN) of the femoral head, occurs in children from 2 to 14 years old, with a peak age of onset of 5 years old. It is five times more common in boys than in girls.\(^2-5\) The incidence of slipped capital femoral epiphysis (SCFE) peaks at 13\(^{1/2}\) years old among boys and 12 years old among girls, in association with the onset of puberty. This condition is nearly twice as common in boys.\(^6\)

### Anatomy of the Hip and Femur

#### Skeletal Anatomy

The femur is the longest and strongest bone in the human body and is routinely subjected to substantial forces during powerful muscle contraction and weight transmission. It consists of the femoral head, neck, and shaft. The femoral head is firmly seated in the acetabulum, reinforced by the labral cartilage. The well-developed capsule, overlying ligaments, and proximal musculature of the lower extremity add strength to the joint (Fig. 49.1). Structurally, the femoral neck serves as an oblique strut between the femoral head, neck, and shaft. The femoral head is firmly seated in the acetabulum, reinforced by the labral cartilage. The well-developed capsule, overlying ligaments, and proximal musculature of the lower extremity add strength to the joint (Fig. 49.1).

As the external iliac artery passes beneath the inguinal ligament, it becomes the common femoral artery. At this point, the artery is located midway between the anterior superior iliac spine (ASIS) and the symphysis pubis. Approximately 3 to 4 cm distal to the inguinal ligament, the deep femoral artery branches off. The deep femoral artery is predominantly responsible for the vascular supply of the femur. It runs posterolaterally to the superficial femoral artery, supplies the hamstrings, and terminates in the distal third of the thigh as small branches pierce the belly of the adductor magnus. The superficial femoral artery continues to pass along the anteromedial aspect of the thigh and terminates at the junction of the middle and lower thirds of the thigh. Here, the superficial femoral artery passes through the adductor hiatus and becomes the popliteal artery.

#### Venous System

In the proximal two-thirds of the thigh, the common and superficial femoral veins lie adjacent to the common and superficial femoral arteries. At the inguinal ligament, the common femoral vein is posterior and medial to the common femoral artery and moves to the lateral position as it passes distally. The deep femoral vein and the greater saphenous vein are the two main tributaries to the common and superficial femoral veins. The deep femoral vein and artery run in parallel as the vein joins the superficial femoral vein just distal to the inguinal ligament. The greater saphenous vein arises in the dorsum of the foot and ascends anterior to the medial malleolus. This vein is relatively superficial as it passes up the medial aspect of the leg to join the common femoral vein distal to the inguinal ligament.

#### Nerves

The femoral and sciatic nerves are the major nerves within the thigh. The femoral nerve is located midway between the anterior superior iliac spine (ASIS) and the symphysis pubis. Approximately 3 to 4 cm distal to the inguinal ligament, the common femoral artery becomes the popliteal artery.

Knowledge of the major muscle actions offers insight into common injury patterns and deformities (Fig. 49.3).
The posterior femoral branch gives off the saphenous nerve, which supplies sensation to the skin along the medial aspect of the lower part of the leg. The posterior branch also supplies motor function to the muscles of the quadriceps femoris group.

The sciatic nerve is the largest peripheral nerve in the body. It arises from the sacral plexus. The sciatic nerve exits the pelvis through the greater sciatic foramen and travels through the posterior thigh; it extends from the inferior border of the pyriformis muscle to the distal third of the thigh. The sciatic nerve gives off articular branches that supply the hip joint. In the thigh, muscular branches innervate the adductor magnus and hamstring muscles. Just proximal to the popliteal fossa, the sciatic nerve divides to form the tibial and common peroneal nerves.

### Pathophysiology

**Osteoporosis of the Femur**

Osteoporosis is the leading cause of hip fracture. The pathophysiology of osteoporosis is not completely understood, but strong associations with hormonal changes related to aging, genetic predisposition, vitamin D deficiency, lack of physical activity, and smoking have been recognized. Severe osteoporosis and hip fractures are most common in elderly white women; however, a decrease in bone density after age 30 is seen across all demographic groups. The trabeculae of the femoral head and neck strengthen the bone and support the large mechanical forces produced across the hip joint. As osteoporosis begins and then progresses, these trabeculae disappear. This loss of trabeculae weakens the bone and increases the risk of fracture. Osteoporosis currently affects

Osteoporosis is the leading cause of hip fracture. The pathophysiology of osteoporosis is not completely understood, but strong associations with hormonal changes related to aging, genetic predisposition, vitamin D deficiency, lack of physical activity, and smoking have been recognized. Severe osteoporosis and hip fractures are most common in elderly white women; however, a decrease in bone density after age 30 is seen across all demographic groups. The trabeculae of the femoral head and neck strengthen the bone and support the large mechanical forces produced across the hip joint. As osteoporosis begins and then progresses, these trabeculae disappear. This loss of trabeculae weakens the bone and increases the risk of fracture. Osteoporosis currently affects...
more than 10 million people in the United States and is projected to affect approximately 14 million adults older than 50 years by the year 2020. The number of hip fractures attributable to osteoporosis is expected to be 6.3 million by the year 2050, although the incidence in women has been decreasing in recent years.1

Fractures and Trauma of the Femur and Hip

The vast majority of hip fractures occur in elderly patients with preexisting bone disease who sustain low-energy trauma, usually a ground-level fall. In young healthy individuals, major trauma, such as a motor vehicle collision (MVC) or a fall from a significant height, is responsible for most fractures. Twenty percent of patients with hip fracture die during the first year after the injury, mostly from sequelae of the fracture rather than the fracture itself. One-third of patients require nursing home placement, and less than one-third regain their pre-fracture level of physical function. The economic impact of these fractures is enormous.

Osteoarthritis of the Hip. A large percentage of the American population experiences chronic pain from degenerative osteoarthritis of the hip due to the significant weight-bearing responsibility. Osteoarthritis ranks fifth in health impact (measured in years lost to disability) in high-income countries and ninth in low- and middle-income countries. Disability often results from persistent pain and limited physical mobility. The progression of osteoarthritis can be demonstrated with serial radiographs of the affected hip (Fig. 49.5); however, radiographic findings do not necessarily correlate with symptoms.
Avascular Necrosis

When a patient has an increasingly painful hip, buttock, thigh, or knee and no history of recent trauma, AVN of the femoral head should be considered. AVN has been referred to as aseptic necrosis, ischemic necrosis, and osteonecrosis. It is the result of ischemic bone death of the femoral head after compromise of its blood supply (Fig. 49.6). AVN is bilateral in 40% to 80% of patients. It is common in relatively young patients, the mean age at diagnosis being 38 years old. Although a specific causative disorder is not identified in 20% of cases, known atraumatic causes include chronic corticosteroid therapy, chronic alcoholism, hemoglobinopathy (eg, sickle cell anemia), dysbarism, and chronic pancreatitis. AVN is an emerging complication associated with human immunodeficiency virus (HIV) infection. It is unclear whether the pathologic agent is the virus itself or the treatment.

Traumatic AVN, a subacute manifestation after hip dislocation or femoral neck fracture, is a direct result of disruption of the blood supply to the femoral head. It is more common in males and African Americans. The incidence of AVN as a subacute complication is clearly related to both the initial degree of trauma and the amount of time the femoral head remains dislocated. Multiple studies have demonstrated a relationship between the length of time the hip is dislocated and the rates of AVN: it develops in about 5% of patients if reduction is performed within 6 hours and as many as 60% when reduction occurs after 12 hours. For this reason, hip dislocation is an orthopedic emergency. The emergency clinician should perform reduction of the hip if orthopedic consultation will be delayed.

Even with optimal treatment, femoral neck fractures are complicated by AVN in up to 20% of cases. They are essentially intra-articular fractures. Immediately after fracture, bleeding from the site may cause high intracapsular pressure and a tamponade effect on the femoral head, thereby impairing the blood supply. If the bone fragments are not impacted, synovial fluid will lyse the blood clot, which prevents the development of capillary buds and the scaffolding needed for osseous repair. In contrast, intertrochanteric and subtrochanteric fractures are located in an area with a rich extracapsular arterial supply; therefore, AVN rarely complicates these fractures.

Myositis Ossificans

Myositis ossificans (heterotrophic ossification) is pathologic bone formation at a site where bone is not normally found. Traumatic myositis ossificans results most commonly from a direct blow to muscle. Bleeding into the muscle after trauma produces a local hematoma with subsequent new bone formation within it. The thigh and hip muscles are often involved. This inappropriate response can also result from repeated minor trauma. The ossific mass might be palpable and might limit motion, depending on its location.

Myositis occurs in up to 20% of patients undergoing medical evaluation for thigh contusions, likely related to the severity of the injury. The incidence of myositis ossificans after hip surgery is approximately 2%, and these lesions are clinically significant in 10% to 20% of cases. Increased susceptibility to myositis ossificans has been described in persons with hemophilia and other bleeding disorders in conjunction with soft tissue injury. Radiographically, myositis ossificans appears as irregularly shaped masses of heterogenous bone in the soft tissues around the joint or along fascial planes (Fig. 49.7). It can be seen as early as 10 to 21 days after injury, but radiographic evidence typically lags behind the onset of symptoms by weeks. Its appearance might simulate primary bone neoplasm, especially when the periosteum is involved. Osteosarcoma and periosteal osteogenic sarcoma should be considered in the differential diagnosis. Computed tomography (CT) can sometimes be helpful in distinguishing between neoplasm and myositis ossificans, because the lesions of myositis ossificans begin to calcify at the periphery and progress toward the center.
and those of osteosarcoma begin to calcify at the center first. Orthopedic follow-up should be arranged for these patients.

Calcific Bursitis and Calcifying Peritendinitis

Calcification surrounding tendons and bursae or occurring in the joint capsule is referred to as calcific bursitis or calcifying peritendinitis. The cause of these lesions is unknown. No relationship has been documented between the radiographic findings and acute symptoms. Calcific bursitis of the hip is uncommon, but when it does occur, it most frequently affects the trochanteric bursa (Fig. 49.8). Other possible affected areas include the gluteal muscles and the hip flexors and adductors. The bursal calcification is seen on radiographs as an amorphous, poorly marginated line that is clearly separate from the cortex of the femur.

Neoplastic Disease in the Hip

The most common neoplastic disease of bone is metastatic, generally from breast, kidney, lung, thyroid, or prostate tumors. Primary bone lesions also occur, the most common being osteoid osteoma (Fig. 49.9). Bone lesions can be osteoblastic or osteolytic. Patients come to the ED with significant bone pain or a large mass,

Fig. 49.7. Myositis ossificans of the proximal end of the femur. Lesions can be immature or mature such as this one, with well-organized calcifications.

Fig. 49.8. Calcific trochanteric bursitis. Faint calcification (arrow) in the region of the trochanteric bursa is visible along the lateral cortex of the greater trochanter. (From Harris JH, Harris WH, Novelline RA: The radiology of emergency medicine, ed 3, Baltimore, 1993, Williams & Wilkins.)

Fig. 49.9. Classic radiographic appearance of a solitary osteochondroma of the femur as seen in the anteroposterior (A) and frog leg lateral (B) views. This lesion is a cartilage-capped bony excrescence, typically arising from the cortex of long tubular bones. (From Harris JH, Harris WH, Novelline RA: The radiology of emergency medicine, ed 3, Baltimore, 1993, Williams & Wilkins.)
such as a solitary osteochondroma that has become irritated or painful (Fig. 49.10). Neoplasms place the patient at higher risk for pathologic fracture, especially if the lesions are large or lytic or have eroded the cortex.

**CLINICAL FEATURES**

**History**

Injuries and pathologic conditions involving the femur are commonly dictated by age and gender. Because the femur is strong and can withstand the normal “bumps” of everyday life, the complaint is commonly related to a traumatic incident. A detailed description of antecedent trauma or other precipitating events is often helpful, because details of the mechanism of injury can aid in predicting injury patterns. Although direct trauma is a common cause of injuries, a thorough past medical history should be obtained, because it might provide meaningful clues. Patients who recently altered their level of physical activity or exercise routine could have a stress fracture. Information about systemic illnesses or metabolic disorders should be elicited. A previous cancer diagnosis and its treatment with irradiation or chemotherapy could be a predisposing factor, providing clues about pathologic fractures. Any past steroid use, including inhaled steroids, is important to identify because it places patients at higher risk for AVN of the femoral head. A linear relationship has been recognized between cumulative steroid dose and the incidence and severity of osteoporosis and hip fracture.

Determination of the location of the patient’s pain is paramount, because true hip joint pain can be perceived as groin pain. Children with hip pathology often have knee pain as the sole presenting complaint. The review of systems should include information that can help distinguish hip or femur pathology from another cause of the pain. Atypical causes of hip or groin pain include nephrolithiasis, pelvic inflammation, infection, malignancies, inguinal and femoral hernias, and lymphadenopathy. A history of low back pain suggests radiculopathy as the cause of the patient’s pain. The differential diagnosis of hip pain without obvious fracture on radiographs is listed in Box 49.1.

The history should also focus on comorbid conditions and injuries. Elderly patients with a hip fracture sustained in a fall at home might be unable to summon help for hours to days. They often have concomitant dehydration, electrolyte abnormalities, rhabdomyolysis, and renal insufficiency. They require a thorough evaluation and resuscitation before surgery is considered. In addition, the reason for the fall should be determined, because it may reveal other comorbid conditions (eg, syncope, cardiac dysrhythmias, polypharmacy, and/or alcoholism). Sedative and antihypertensive medications predispose elderly patients to falling and should be prescribed carefully. With a fall, elderly patients might sustain additional injuries, most commonly, the fracture of a vertebral body or wrist. Cervical spine and intracranial injuries should also be considered. Forty percent to 75% of young patients with a hip fracture resulting from high-energy mechanisms have concomitant injuries.

**Physical Examination**

Management principles for injuries of the hip and femur are the same as those for traumatic injuries elsewhere in the body. Because patients with femoral pathology can have a multitude of presentations, a thorough physical examination is important. Due to the major forces that are sustained in multisystem trauma, hypotension is a problem commonly encountered during the
**DIFFERENTIAL DIAGNOSIS**

A detailed history and physical examination often elicit the cause of the pain. Patients with hip and thigh pain can have pain referred from a multitude of other areas. If a fracture is not apparent, emergency clinicians should consider the causes outlined in **Table 49.1** in patients who are experiencing hip or thigh pain. In the setting of trauma, it is imperative that a thorough physical examination be done to exclude referred pain and associated injuries. Most patients who arrive in the emergency department (ED) with hip or thigh pain provide a clear history of a traumatic event. Hip or knee pain in the young, in athletes, and in the elderly deserves investigation, even when minimal or no trauma has been reported. This diverse patient population commonly has an occult hip disruption, occasionally involving the femur. Senile osteoporosis is the leading cause of femoral neck fractures after minor trauma; pathologic fractures of the femur can result from metastatic, metabolic, or endocrine disease.

**DIAGNOSTIC TESTING**

**Radiographic Evaluation**

Plain radiographs, including true anteroposterior and lateral views of the femur, are usually adequate for the evaluation of potential fractures (**Fig. 49.11**). The femur should be in as much internal rotation as possible. Fracture lines can be very subtle, particularly in the femoral neck. Three methods are useful for identifying inconspicuous fractures:

- First is the use of Shenton’s line, which is described in a subsequent section on hip dislocations.
- Second is a search for the normal S and reverse S curves seen on radiographs of non-fractured hips. In normal anatomic position, the convex outline of a normal femoral head smoothly joins the concave outline of the femoral neck. This produces an S curve and a reverse S curve, regardless of the orientation of the radiographic projection. In searching for a fracture of the femoral neck, the medial and lateral cortical margins of the femoral head and neck should be carefully examined for those curves (**Fig. 49.12**). A fracture produces a tangential or sharp angle, indicating disruption of the normal anatomic relationship.
- The third method, useful in the evaluation of seemingly unremarkable hip radiographs, is tracing the trabecular lines as they pass from the femoral shaft to the femoral head. Disruption of these lines as they pass through the fracture site is often the only, albeit subtle, clue.

In impacted femoral neck fractures, the neck cortex is driven into the cancellous femoral head. Bone impaction lends a certain inherent stability (**Fig. 49.13**). If a fracture is found, radiographs of the knee should be obtained as well. It is a basic orthopedic principle to image the joint above and below any fracture, because concomitant injuries are common.

**BOX 49.1**

**Differential Diagnosis of a Painful Hip Without Obvious Fracture**

- Referred pain (lumbar spine, hip, or knee)
- Avascular necrosis (AVN) of the femoral head
- Degenerative joint disease or osteoarthritis
- Herniation of a lumbar disk
- Diskitis
- Transient synovitis of the hip
- Septic arthritis
- Bursitis
- Tendonitis
- Ligamentous injuries of the knee or hip
- Occult fracture
- Slipped capital femoral epiphysis (SCFE)
- Perthes’ disease
- Tumor (lymphoma)
- Deep venous thrombosis
- Arterial insufficiency
- Osteomyelitis
- Iliopsoas abscess
- Retropatellar hematoma
- Inguinal hernia
- Inguinal lymphadenopathy
- Genitourinary complaints
- Sports-related hernia

Initial resuscitation. Although hypotension might result from the loss of up to 3 units of blood into the thigh of a patient with a femoral fracture, other conditions (cardiac, pulmonary, intra-abdominal, and pelvic trauma) must be considered. Hemorrhagic shock from an isolated femoral fracture should be a diagnosis of exclusion. Hypotension, neurovascular compromise, or suspicion for multiple injuries are indications for transfer to a specialized trauma center.

After life-threatening conditions have been addressed, the injured extremity should be evaluated carefully. The position of the leg offers a clue to radiographic findings. External rotation, abduction, and shortening suggest a displaced femoral neck fracture. External rotation with shortening suggests an intertrochanteric fracture. Visual inspection might reveal pallor, ecchymosis, asymmetry, or deformity. The presence of abrasions, lacerations, and open wounds alters the management of concomitant injuries.

A detailed history and physical examination often elicit the cause of the pain. Active and passive range of motion and assessment of muscle strength, though offering important information, are frequently limited by pain. A detailed neurovascular assessment is vital, as femoral nerve and arterial injuries often occur in conjunction with subtrochanteric and femoral shaft fractures or anterior hip dislocations. The sciatic nerve can be injured with a hip fracture or posterior hip dislocation. Neurologic examination includes evaluation of light touch and pinprick sensation. The examination should also assess for any signs of arterial injury indicating a rapidly expanding hematoma. Femoral, popliteal, dorsalis pedis, and posterior tibial pulses should all be assessed. Comparative blood pressures obtained by Doppler examination in the injured and uninjured extremities (arterial pressure index) could be useful in diagnosing occult femoral arterial injuries. If the systolic pressure in the affected extremity is 90% or less (ratio less than 0.9) than that in the unaffected extremity, additional diagnostic studies should be performed. Those studies include Doppler flow ultrasound imaging, computed tomography angiography (CTA), or angiography alone. The ankle-brachial index (ABI) also can be determined by comparing the systolic pressures of the affected extremity and the ipsilateral arm. An index less than 0.9 necessitates further diagnostic studies. Although compartment syndrome of the thigh is rare, consideration should be given to this diagnosis if the patient sustained a severe mechanism of injury and has tense swelling in the thigh.
Occult Hip Fracture

If radiographs do not show an overt fracture or injury, the care provider should assess gait. Inability to ambulate or difficulty in weight bearing suggests an occult fracture. Up to 10% of all hip fractures are radiographically “occult” on plain films. Failure to detect these injuries increases the risk of death, the risk of subsequent displacement of the fracture, and the incidence of AVN. When a painful hip prevents ambulation and plain radiographs do not reveal a fracture, advanced imaging (CT or magnetic resonance imaging [MRI]) is necessary (Fig. 49.14). Elderly patients with unexplained hip pain lasting more than 3 weeks might be harboring an occult fracture even if they continue to walk. T1-weighted MRI will reveal a fracture that was imperceptible at the time of injury with 100% accuracy and has been found to be cost-effective compared with other strategies. MRI is superior to CT and remains the “gold standard” for diagnosing occult hip fractures and helps guide treatment decisions (see Fig. 49.12).

Bone scans have been useful in these patients, but they lack adequate sensitivity. To identify most occult fractures, this type of scan should be delayed for 72 hours after the injury, which limits its use in the emergency care setting.

**MANAGEMENT**

Patients with femoral pathology need hemodynamic stabilization. Because of the risk of blood loss—from both the injury and its operative repair—patients with traumatic fracture of the hip or femur should be typed and crossmatched for at least 2 units of blood. Hemodynamic instability can result from dehydration and the loss of up to 3 units of blood into the fracture site. Operative repair should be performed after the patient is resuscitated and in optimal preoperative condition. The preoperative stabilization of an elderly patient with a hip fracture may require a multidisciplinary approach from emergency medicine, orthopedics, internal medicine, cardiology, and anesthesiology. Comprehensive programs co-managed by geriatricians and orthopedic surgeons have been shown to improve short-term outcomes for the elderly with hip fractures and might even lower the mortality rate, highlighting the importance of the medical management of these complex patients.

**Traction and Immobilization**

If prehospital personnel suspect a femoral fracture, they often place a Hare splint, Sager splint, or similar device that applies traction to the leg before transporting the patient. This management strategy is popular, because it provides pain relief, immobilization, and limits blood loss. However, great care should be taken to ensure the proper use of these devices. Prolonged traction while other injuries are being assessed and managed can cause or worsen serious neurologic injury in the thigh. Traction used in the field for transport can cause skin breakdown at pressure points and might produce potentially damaging tension on the nerve. The

femoral and sciatic nerves are more likely to be injured from traction or during surgery than from a femoral fracture.

Contraindications to the use of traction splints include pelvic fractures, patellar fractures, ligamentous knee injuries, and tibia or fibula fractures. In the prehospital setting, traction should not be applied to any open fracture that has exposed bone. Such reduction pulls grossly contaminated bone fragments back into the wound before adequate débridement. A study that evaluated patients with multisystem trauma in whom traction splints were placed in the field for femur fractures showed that up to 38% had contraindications to the splints that were placed.

With or without traction, the injured extremity should be immobilized when the patient is moved, to prevent further damage from mobile bone fragments. In the prehospital setting, this can be achieved with simple splinting. In the ED, maintaining the leg in slight flexion at the hip reduces intracapsular pressure, whereas extension of the leg increases pressure and the potential for ischemic necrosis of the femoral head. Therefore, traction for proximal femur fractures should be discontinued once the patient has arrived in the ED. The leg can be supported in a position of comfort with a pillow placed under the thigh. The theoretic advantages for continuation of traction in the ED are pain control and fracture reduction, making operations easier to perform. This is likely true for patients with femoral shaft fractures; however, a Cochrane systematic review that looked at preoperative traction for fractures of the proximal femur in adults found no evidence to support these proposed advantages.

Open Fracture Care

By definition, an open fracture is any fracture in which a break in the integrity of the skin and soft tissue allows communication with the fracture and its hematoma. Any nearby wound or break in the skin must be considered to communicate with the fracture. The three categories of open fractures are described in Table 49.2.

A bone piercing from the inside outward often causes only a small wound, after which the contaminated bone tip slips deceptively back into the soft tissue. Open wounds should be irrigated and then covered with sterile saline-moistened gauze.

For all type I open fractures, a first-generation cephalosporin (such as, ceftazolin, 1 g) should be administered intravenously. Types II and III might require additional gram-negative coverage depending on the amount of devitalized tissue and the extent of involvement of the groin and its gram-negative skin flora. This additional coverage could be provided by an aminoglycoside (such as, tobramycin, 1.5 mg/kg). The use of perioperative first-generation cephalosporins reduces the risk of postoperative infection even in patients with closed fractures. Great care should be taken to identify tetanus-prone wounds so that appropriate prophylaxis can be provided with tetanus immune globulin when indicated. Immunization status should be verified in all patients and updated as needed.

Compartment Syndrome

Because of the thigh’s larger volume, compartment syndrome within the thigh is far less common than in the lower part of the leg. A large amount of bleeding into the thigh compartment is required before the pressure rises above capillary perfusion pressure. When compartment syndrome does occur in the thigh, only 50% of the cases are associated with a femur fracture. It is difficult to clinically differentiate the expected swelling after an injury from early compartment syndrome. Clinical examination and the use of direct pressure measurements can detect the development of compartment syndrome at an early stage.

Pain Management

Systemic Analgesia

Pain control in EDs is often inadequate. For patients with femoral fractures, opioid analgesia is often indicated in combination with other pain-relief strategies. In addition to parenteral medications, other pain-relieving strategies include immobilization of the injured extremity, placement of the injured extremity in a position of comfort, and the consideration of local analgesia in the form of nerve blocks.

Pharmacologic Approaches

The classic pharmacologic treatment for pain management in patients with traumatic femoral injuries is opioid analgesics. Morphine, fentanyl, and hydromorphone are all acceptable options. Meperidine should not be used because of unacceptable side effects. Pentazocine is contraindicated in the elderly because of its central nervous system (CNS) effects (eg, lowered seizure threshold). Nonsteroidal antiinflammatory drugs (NSAIDs) can also be difficult to titrate, especially in the elderly, due to their renal and gastrointestinal side effects.

Femoral Nerve Block

The femoral nerve block is an excellent option as an adjunct or alternative to systemic analgesics in patients at risk for hypotension. Femoral nerve blocks significantly decrease the time to the lowest pain score compared with intravenous narcotics, and patients require significantly lower doses of narcotics. The block can be created with the assistance of a peripheral nerve stimulator to localize the nerve or bedside ultrasound to directly visualize the nerve before the anesthetic is injected. The procedure can also be performed by emergency clinicians without the assistance of peripheral nerve stimulators or ultrasound. If a long-acting anesthetic such as bupivacaine is used, the expected onset of analgesia is within 30 minutes and its duration is 6 to 8 hours.

Careful neurovascular examination should be performed and documented before the femoral nerve block is performed. After the nerve block procedure, continued assessment of the femoral muscular compartments is advisable to check for the development of compartment syndrome. If an injury is considered at especially high risk for compartment syndrome, orthopedic surgery consultation should be obtained before the block, and measurement of compartment pressures after the block should be considered. Because the sciatic nerve innervates the compartments of the

lower limb, a femoral nerve block will not mask the clinical presentation of compartment syndrome in the lower leg.

**Hip Arthroplasty**

The most common indication for total hip arthroplasty (THA) is joint failure resulting from severe osteoarthritis. Other indications include rheumatoid arthritis, some types of hip fracture, AVN, and certain tumors. Arthritis associated with Paget’s disease, trauma, ankylosing spondylitis, and juvenile rheumatoid arthritis is also relative indications for total or partial hip arthroplasty.

THA provides an immediate, substantial reduction of pain and improvement in functional ability and overall quality of life. A 10-year follow-up study of patient outcomes, including gait, perception of pain, physical mobility, sleep patterns, and energy scores, showed positive results in more than 90% of cases. Despite the tremendous success of THA, numerous complications have been reported. The most common is aseptic loosening of the prosthesis. Others include component wear, infection, adjacent femoral fractures, deep vein thrombosis, and postoperative dislocation of the femoral component. In general, flexion past 90 degrees, adduction, and internal rotation place the hip at risk for dislocation. This combination can occur when patients bend at the waist (eg, to sit on a low toilet or to get out of a chair) or cross their legs (Fig. 49.15).-Fractures of the Hip and Femur

**Avulsion Fractures**

The incidence of avulsion fractures is increasing as a result of the growth of competitive sports participation, especially in teenage athletes. The muscular origin of this type of injury commonly involves the pelvic apophyses, which might not fully ossify until age 25. Avulsion at the site of the growth plate is the result of sudden maximal muscular exertion. It can occur with rapid acceleration or sudden changes in speed or direction. The athlete classically experiences a sudden piercing pain at the site of injury, along with a “snapping” or “popping,” and frequently falls to the ground because of the intensity of this pain. The pain of avulsion injuries of the hip can manifest as referred pain to the thigh; these fractures are most common in adolescents and young adult athletes. As depicted in Figure 49.16, avulsion at the ASIS involves the separation of a thin piece of bone as the sartorius muscle suddenly contracts (see Fig. 49.16A). The anterior inferior iliac spine (AIIS) is avulsed by the rectus femoris, and the hamstring group can displace the ischial tuberosity (see Fig. 49.16B). Avulsion fractures of the ASIS and AIIS are managed nonoperatively. Treatment of avulsion fractures of the ischial tuberosity is more controversial. Most experts recommend conservative treatment for avulsion injuries with less than 2 cm of displacement. Fractures with more than 2 cm of displacement might benefit from operative fixation to prevent nonunion, as well as union achieved by exuberant callus formation.

**Proximal Femoral Fractures**

Fractures of the proximal end of the femur are classified on the basis of their relationship to the hip capsule (intracapsular or extracapsular).
Femoral Neck Fractures

Classification. Although several classification systems have been used to describe these fractures, they have been abandoned because of poor inter-rater reliability and limited clinical utility. Currently, femoral neck fractures should be classified as either nondisplaced or displaced.

Between 15% and 20% of all femoral neck fractures are nondisplaced fractures. The fracture line is often very subtle. Techniques that allow detection of subtle fracture lines are useful for this reason. Evaluation of the continuity of the subcapital cortical lines, search for an indistinct broad band of increased subcapital density, and identification of the S and reverse S radiographic curves (see Fig. 49.12) leads to the correct diagnosis in most cases. In impacted femoral neck fractures, the neck cortex is driven into the cancellous femoral head. Bone impaction lends a certain inherent stability (see Fig. 49.13). Because of this stability, two management approaches have been advocated: internal fixation and early ambulation. Internal fixation reduces the length of hospital stay and improved rehabilitation and has become the preferred treatment modality. Without impaction, a nondisplaced femoral neck fracture is unstable and will become displaced without internal fixation.

On initial evaluation, a patient with a displaced fracture of the femoral neck lies with the limb externally rotated, abducted, and slightly shortened. The diagnosis is easily confirmed with plain hip films. To avoid further disruption of the blood supply to the femoral head, range-of-motion assessment should be deferred. Treatment of these displaced fractures consists of open reduction and internal fixation (ORIF), hemiarthroplasty, or THA. In all displaced femoral neck fractures, the femoral head is rendered largely avascular, and signs of AVN and collapse might develop over the ensuing several years. The mortality rate during the first year after a femoral neck fracture is 14%, compared with 9% for the control population. Factors affecting the mortality rate include age, male sex, psychiatric illness, end-stage renal disease, and congestive heart failure. Institutionalized patients have a death rate up to three times higher than noninstitutionalized patients. Complications can be minimized by early reduction, stable internal fixation, early ambulation, and close attention to medical comorbidities.

The two major complications of femoral neck fractures are AVN and nonunion. AVN is the most common complication, despite optimal treatment, because of the complex arterial anatomy. Deep infection in the form of osteomyelitis or septic arthritis is more common with femoral neck fractures, because the fracture line extends into the joint. The use of perioperative antibiotics dramatically reduces the rate of infection. Pulmonary embolism is another significant complication and is the leading cause of death 7 days after fracture. Anticoagulation is recommended for at least 10 days after any hip surgery in patients without significant contraindications. Fondaparinux is an effective anticoagulant in this setting.

Intertrochanteric Fractures

The fracture line of intertrochanteric fractures extends between the greater and lesser trochanters of the femur. These injuries are considered extracapsular fractures. The fracture line extends through cancellous bone, which has an excellent blood supply. The hip’s short external rotators remain attached to the distal fracture fragment, and the internal rotators are attached to the proximal fracture fragment. The strong action of the iliopsoas muscle causes the leg to be shortened and externally rotated.

A large number of classification systems for intertrochanteric fractures have been proposed to predict the possibility of achieving and maintaining stable reduction. A useful system designates the fracture according to the number of bone fragments (Fig. 49.17).

Intertrochanteric fractures often are associated with other, distant, fractures caused by the same trauma, such as a fall. Associated fractures of the distal radius, proximal humerus, ribs, and lumbar and thoracic spine are often overlooked because the femoral fracture distracts the attention of both patient and

![Fig. 49.17](image-url) The number of parts produced by the fracture classifies intertrochanteric fractures.

A. Two-part fractures have one part connected to the femoral head and a second part attached to the shaft. B. The greater or lesser trochanter also is fractured with three-part fractures. A greater degree of instability is produced because the attached muscles continue to act on the fractured trochanter.

C. Four-part intertrochanteric fractures involve both trochanters.
clinchian. Nutrition, chronic diuretic use, and decreased oral intake prior to the injury contribute to dehydration, and greater need for resuscitative fluids.

A substantial majority of intertrochanteric fractures require internal fixation. Such fixation brings rapid mobilization, decreased hospital length of stay, reduced mortality, and improved function. The procedure should be performed on an urgent rather than an emergent basis, because the patient should be fully resuscitated prior to operative repair. The risk of death increases when the patient is taken to the operating room on the day of injury; however, early repair within 24 to 48 hours improves the 1-year mortality rate. Preoperative medical optimization by multidisciplinary medical teams can decrease the 1-year mortality rate in these patients.

Patients with intertrochanteric fractures have a mortality rate of up to 30% in the first year. Life expectancy returns to normal among patients who survive that year. Survival is most commonly related to the patient’s age and preexisting medical conditions. Additional risks associated with operative treatment include mechanical failure, implant migration, and infection. Mechanical failures and nonunion are much more common in patients with unstable fractures and those whose fractures were not reduced adequately. Approximately half of patients who sustain these fractures are eventually able to regain their original level of ambulation. Yearly infusion of zoledronic acid (a bisphosphonate) beginning within 90 days after hip fracture repair reduces the incidence of new fractures and decreases the mortality rate.

Isolated Fractures of the Greater or Lesser Trochanter

Fractures of the greater or lesser trochanter are rare. They occur in women more often than in men and are the result of a fall directly onto the trochanter or avulsion by the iliopsoas muscle. There may be a comminuted fracture involving only part of the greater trochanter or more subtle impaction of the lateral cortex. If an avulsion is present, the fragments are displaced superiorly and posteriorly (Fig. 49.18).

Subtrochanteric Fractures

Subtrochanteric fractures occur between the lesser trochanter and the proximal 5 cm of the femoral shaft. They may accompany intertrochanteric fractures. The subtrochanteric region is composed almost entirely of cortical bone, which lacks the vascularity important to new bone growth and repair. When fractured, it is more likely to be comminuted than bone with a higher cancellous content. In addition, the greater portion of the biomechanical forces of the femur is transmitted down the curved medial cortex of the femoral shaft. If this cortex is disrupted, the metal hardware undergoes the majority of the stress. This mechanism accounts for the increased incidence of hardware failure when the medial cortex is largely involved.

These fractures characteristically are deformed because of the unbalanced muscle forces. In displaced fractures, the attachments of the iliopsoas, gluteal, and external rotator muscles consistently produce flexion, abduction, and external rotation of the proximal fragment.

Subtrochanteric fractures account for 11% of all fractures of the proximal end of the femur. Although a small percentage of these fractures is caused by gunshot wounds, the usual mechanism of injury is direct blunt trauma. There is a bimodal distribution of injuries. The first group comprises victims of extreme high-energy trauma. In these patients, the subtrochanteric fracture is rarely an isolated injury because of the tremendous force required to produce it. Thirty percent to 50% of patients with subtrochanteric fractures have associated fractures of the pelvis, spine, or other long bones. The second group consists of elderly patients who experience a fall, in whom the fracture occurs through an area of weakened cortical bone. Pathologic fractures from metastatic lesions, Paget’s disease, renal osteodystrophy, osteogenesis imperfecta, and osteomalacia are well-recognized clinical entities in these patients. Stress fractures can occur in this region but are extremely uncommon. Various classification systems for these fractures have been proposed, although none is widely accepted. From a practical standpoint, it is best to define and describe these fractures by location (proximal or distal), angle (transverse or oblique), and the presence of comminution (Fig. 49.19).

Hemodynamic instability can result from blood loss at the fracture site. Although such blood loss can lead to hypovolemic shock, other causes of hypotension in a trauma patient need to be considered due to the forces required to obtain these injuries. Open fractures are rare and, when present, are accompanied by significant soft tissue injury. Vascular and neurologic injuries are also uncommon.

Definitive management of subtrochanteric fractures is a complex issue. Maintaining limb length and controlling rotation are difficult. ORIF is the treatment of choice. However, in the rare case of a severely comminuted or an open, grossly contaminated fracture, nonoperative management might be preferable. Children younger than 10 years old also can be managed nonoperatively. The amount of remodeling and growth stimulation occurring in children of this age usually ensures good results without internal fixation.

The bone in the subtrochanteric region is largely cortical and relatively avascular compared with the cancellous intertrochanteric region. It logically follows that healing is comparatively slow. Comminuted and distal subtrochanteric fractures carry a worse prognosis.

Complications include fat embolism in patients of all ages and the adverse effects of prolonged immobilization in the elderly. The
Femoral Shaft Fractures

Femoral shaft fractures are common injuries in young adults after high-energy trauma. As is the case with other femoral cortical fractures, considerable force is required to produce a fracture in a normal shaft. Automobile and motorcycle crashes, falls, and pedestrian incidents account for a majority of femoral shaft fractures. The femoral shaft usually fails under tensile strain, resulting in a transverse fracture. Higher forces produce varying degrees of segmentation. Open fractures of the femoral shaft are less frequent and are often the result of a gunshot wound. Pathologic fractures occur from a low-mechanism force that produces torsion and spiral fractures.

Stress Fractures

Stress fracture of the femoral neck was first reported in 1905 by Blecher. Stress fractures or reactions occur when normal bone is subjected repeatedly to submaximal forces. This recurring stress stimulates the bones to remodel and strengthen. In a stress fracture, osteoblasts are unable to lay down new bone and remodel fast enough, so the bone fails. Stress fractures can also occur in diseased bone when it is subjected to repeated minimal stress.

The symptoms of a stress fracture of the femoral neck often are so subtle that they can be mistaken for muscle strain or an overuse injury. Early symptoms frequently include morning stiffness and aching in the hip on the first steps after a period of rest. The pain gradually increases during prolonged exercise and may reach the point at which weight bearing becomes impossible. Patients complain of pain in the groin or along the medial aspect of the thigh toward the knee.

Pathophysiology. Stress fracture of the femoral neck is based on involvement of the compressive or tensile aspect. Compressive-side fractures involving less than half of the cortex are inherently stable and can be treated conservatively with partial weight bearing with crutches. Tension-side fractures and compressive-side fractures involving more than half the cortex are considered unstable and at risk for displacement. These fractures should be treated operatively with screw fixation.  

Dislocations and Fracture-Dislocations of the Hip and Femur

Hip Dislocations

Dislocations and fracture-dislocations of the hip are true orthopedic emergencies. The hip joint possesses impressive inherent strength and stability; therefore, considerable force is required to produce these injuries. With this understanding, a hip dislocation serves as a "red flag" for multisystem injury and should prompt a diligent search for other injuries. As many as 70% of patients with a dislocation have an associated acetabular fracture. Knee fractures, ligamentous injuries, and dislocations are present in up to 30% of patients who have sustained a hip dislocation. It is highly recommended that, in the presence of this type of injury, patients be managed as major trauma victims. The incidence of hip fractures and dislocations is increasing in young patients, often as a result of high-energy trauma. Up to 50% of children with a hip dislocation have fractures elsewhere. In small children, dislocation of the hip is more common than femoral neck fractures. The force required to dislocate a pediatric hip is much less than that required in an adult because the acetabulum is less completely developed. Seemingly negligible trauma, such as tripping or a minor fall, can dislocate the femoral head in a young child. In a school-age child, athletic injuries are the major cause of traumatic hip dislocation. In the teenage years, MVCs predominate as the cause of hip dislocations.

Traumatic hip dislocations occur primarily in patients sustaining severe multisystem trauma, most often as a result of a high-speed MVC. Failure to use seat belts is a significant risk factor. Less common mechanisms include falls, sports injuries, and pedestrians struck by automobiles.

Posterior dislocations are almost always the result of MVCs. A seated vehicle occupant typically has the hip adducted, flexed, and internally rotated at the time of impact. As the knee strikes the dashboard, the force is transmitted through the femoral shaft to the femoral head. With sufficient force, the femoral head dislocates posteriorly. Anterior dislocations result from forceful extension, abduction, and external rotation of the femoral head. These forces lever the head up out of the acetabular cup.

The relationship of the femoral head to the acetabulum is used to classify dislocations into anterior, posterior, central, and inferior types. A fracture-dislocation includes an associated fracture of the acetabulum or femoral head. Posterior dislocations (Fig. 49.21) account for 80% to 90% of dislocations. Anterior dislocations (Fig. 49.22) are seen in 10% to 15% of patients. In anterior dislocations, the femoral head can dislocate medially toward the obturator foramen (obturator dislocation) (Fig. 49.23) or laterally toward the pubis (pubic dislocation) or the iliac crest. Central dislocations, which occur in 2% to 4% of cases, are not true dislocations, because the entire femoral head is forced centrally...
through a comminuted fracture of the acetabulum. Inferior dislocation of the hip associated with inversion of the femoral shaft (luxatio erecta femoris) is a very rare condition that occurs with or without associated trochanteric fracture.11

The position of the injured extremity might provide valuable clues in the evaluation of a hip dislocation. A patient with a posterior dislocation typically holds the hip flexed, adducted, and internally rotated. The knee of the affected extremity rests on the opposite thigh. The extremity generally is shortened, and the greater trochanter and buttock may be unusually prominent. In contrast, a patient with an anterior dislocation holds the hip in abduction, slight flexion, and external rotation, and the leg could appear lengthened. These physical findings might be absent in patients with an associated ipsilateral femoral shaft fracture.

The neurovascular examination should focus on the sciatic nerve and femoral vessels. Sciatic palsy is present in approximately 10% of patients with hip dislocation and most commonly involves the peroneal nerve branch. The most sensitive clinical sign of peroneal nerve palsy is weakness of the extensor hallucis longus; other signs include weakness of dorsiflexion and numbness or tingling over the dorsum of the foot. The femoral vessels and nerve are particularly prone to injury after an anterior dislocation.

Radiologic investigation begins with an anteroposterior view of the pelvis. This view alone will identify a majority of hip dislocations. An anteroposterior pelvis film should be obtained in all trauma patients with the aforementioned deformities. The anteroposterior radiograph should include the entire pelvis and the proximal third of the femur to allow comparison of both hips. When a dislocation is found or suspected, a lateral view of the hip will provide additional definition of the injury.

Although most hip dislocations are seen clearly with these two views, several more subtle radiographic signs can assist emergency clinicians in making a diagnosis. The first indicator involves the position of the lesser trochanter. Because a posteriorly dislocated hip is internally rotated, the lesser trochanter is superimposed on the femoral shaft and is not seen on the anteroposterior projection. By contrast, an anteriorly dislocated hip is externally rotated, and the lesser trochanter appears in profile. The second clue is found in the size of the femoral head. Because a posteriorly dislocated hip is closer than the unaffected side to the x-ray cassette, it appears smaller. The converse is true in anterior dislocations, in which the hip is farther from the x-ray cassette than the contralateral side and is thus appears larger. The third finding relates to the integrity of Shenton’s line (Fig. 49.24), a smooth, curved line drawn on the radiograph along the superior border of the obturator foramen and medial aspect of the femoral metaphysis. Disruption of this line should raise suspicion of a femoral neck fracture or hip dislocation.

Fig. 49.24. Shenton’s line is a smooth curved line drawn along the superior border of the obturator foramen and medial aspect of the femoral metaphysis. Disruption of this line should raise suspicion of a femoral neck fracture or hip dislocation.

An obvious dislocation might distract the clinician from a search for concomitant fractures. Examination of the trabecular pattern can identify associated fractures of the acetabulum and femoral head, neck, or shaft. It is important to identify acetabular fractures before closed reduction is attempted because intraarticular bone fragments could interfere with effective reduction. Although these fractures might make the reduction more difficult, their presence is not a contraindication to the procedure.

Hip dislocations constitute a true orthopedic emergency, and reduction should be performed within 6 hours. The incidence of AVN, traumatic arthritis, permanent sciatic nerve palsy, and joint instability increases logarithmically with the length of time the hip remains dislocated.

The timing and method of reduction depend on the overall condition of the patient, the type of dislocation, and the presence or absence of associated fractures. In cases of simple dislocation, closed reduction should be attempted first. Although some clinicians recommend that this procedure be performed with the patient under general anesthesia, this delay, with its associated increase in the rate of AVN, is not warranted when procedural sedation in the ED is available. If the emergency clinician chooses to attempt closed reduction, the principles of procedural sedation and monitoring should be followed. The primary relative contraindication to closed reduction is the presence of a femoral neck fracture. Another relative contraindication is the presence of fractures in the dislocated extremity, because such fractures preclude application of traction to the limb. Techniques of closed reduction are described next.

Stimson’s technique and the Allis technique have been used most commonly for reduction of posterior hip dislocations (Fig. 49.25). The Allis technique usually is effective for both posterior and obturator dislocations (Fig. 49.26). It is the most commonly
These two techniques are being replaced by new methods that are safer and just as effective: the Whistler and Captain Morgan methods. These techniques use the power of the provider's leg muscles to reduce the hip, instead of relying on lower back and arm strength. The Captain Morgan and Whistler techniques use the provider's knee and arm, respectively, as a fulcrum to apply force and reduce the hip. The Captain Morgan technique has a success rate of 95%, but there are reports that excessive downward force on the ankle has caused ligamentous injuries in the knee.

To perform the Captain Morgan technique for reduction of posterior hip dislocation (Fig. 49.28):
1. Place the patient supine on the stretcher in its lowest position, secure the pelvis to the stretcher with a bed sheet or strap. Place the strap over the ischial wings and pubic symphysis. This prevents you from lifting the patient off the bed and is more effective than having an assistant try to secure the pelvis.
2. Stand at the side of the bed and place one foot up on the bed (like Captain Morgan standing on a rum barrel). If you need additional height, consider using a stable cardiopulmonary resuscitation (CPR) stool.
3. Place the patient's ipsilateral leg over your leg so that your knee is resting in his or her popliteal fossa.

Stimson's technique (Fig. 49.27) uses the weight of the limb and the force of gravity to reduce the dislocation and is relatively atraumatic. Although Stimson's technique generally is effective, placing an acutely and often multiply injured trauma patient in the required prone position could be a challenge. Adequate radiographic clearance of the spine usually has not yet been accomplished, and the administration of sedatives and analgesics to a prone patient has inherent risks.

To perform Stimson's technique for reduction of posterior hip dislocation:
1. Place the patient in a prone position, with the leg hanging over the edge of the bed. The hip and knee are flexed at 90 degrees.
2. Ask an assistant to stabilize the pelvis.
3. Apply steady downward traction in line with the femur.
4. Gently rotate the femoral head while the assistant pushes the greater trochanter anteriorly toward the acetabulum.
5. Once reduction has been achieved, bring the hip to the extended position while maintaining traction.

These two techniques are being replaced by new methods that are safer and just as effective: the Whistler and Captain Morgan methods. These techniques use the power of the provider's leg muscles to reduce the hip, instead of relying on lower back and arm strength. The Captain Morgan and Whistler techniques use the provider's knee and arm, respectively, as a fulcrum to apply force and reduce the hip. The Captain Morgan technique has a success rate of 95%, but there are reports that excessive downward force on the ankle has caused ligamentous injuries in the knee.
4. While holding the ankle in position with slight downward pressure, lift up with both legs to apply traction on the femur and reduce the hip.
5. If traction alone does not work, use your hands to internally and externally rotate the leg to achieve the reduction.

The Whistler technique often works better for practitioners who are of shorter stature and have difficulty getting their leg in proper position for the Captain Morgan technique. In this method, the clinician uses his or her stabilized arm under the ipsilateral knee to lift the leg using the leg muscles.

To perform the Whistler technique for reduction of posterior hip dislocation (Fig. 49.29):
1. Start with the patient lying supine on the bed, and secure the patient’s hips to the bed, as for the Captain Morgan technique.
2. Bend the contralateral leg so that the patient’s knee is flexed 90 degrees and the foot is on the bed.
3. Bend the ipsilateral leg to the same position.
4. Place your arm under the ipsilateral knee and rest it on top of the contralateral knee.
5. Now rotate your body so that you are perpendicular to the patient and looking at his or her feet. This should cause you to squat a little.
6. While holding the patient’s ipsilateral ankle with your other hand, slowly lift up with your legs, while keeping your arm straight and strong. This puts traction on the femur and should reduce the dislocation.
7. If reduction is not achieved with traction alone, use your hand that is on the ankle to internally or externally rotate the leg to achieve the reduction.

Other techniques for closed reduction of posterior hip dislocations include the Rochester method and the traction-countertraction technique.

Closed reduction of a pubic dislocation can be quite difficult. The anterior position of the femoral head will resist flexion, making the Allis technique impossible. The following sequence of maneuvers is recommended.

To perform the technique for reduction of pubic dislocation:
1. Place the patient in the supine position.
2. Apply longitudinal traction in line with the deformity.
3. Hyperextend and internally rotate the hip while an assistant applies downward pressure on the femoral head.

Although prompt anatomic reduction is clearly desirable, multiple attempts at reduction in the ED should be avoided because of potential damage to the articular surface and because the incidence of osteonecrosis increases with the number of attempts at reduction, as well as the duration of the dislocation. Difficulty with reduction is usually the result of incarceration of a tendon, a capsular structure, or an osteochondral fragment that is blocking reduction. In the case of a non-reducible dislocation, closed reduction with the patient under general anesthesia or an open reduction procedure often is required.

After closed reduction, the hip should be tested for stability, which is accomplished by gently taking it through its full range of motion to see whether it will redislocate. After testing has ensured stability, the injured extremity should be placed in a knee immobilizer and an abduction pillow should be applied to prevent repeat dislocation. An anteroposterior radiograph of the pelvis should be obtained to verify the adequacy of reduction. The radiograph should be inspected carefully to verify that the femoral head is in the acetabulum, the shaft of the femur is in neutral position, Shenton’s line is intact, and the profile of the lesser trochanter is well visualized. The intra-articular space should be symmetrical and, when measured, of the same depth as in the unaffected joint. Asymmetry signals an entrapped intra-articular fragment and is an indication for CT imaging.

The precarious blood supply to the femoral head is particularly important with regard to the long-term consequence of hip dislocations. The development of AVN of the femoral head has been reported in 1% to 17% of dislocations. Other risk factors for the development of AVN include the total dislocation time, the severity of the injury, the number of reduction attempts, and the presence of comorbid conditions.

Fracture-Dislocation of the Femoral Head

Hip dislocations can be associated with fractures of the femoral head (Fig. 49.30A). Femoral head fracture occurs in 35% to 55% of anterior hip dislocations and in 10% to 16% of posterior hip dislocations. These injuries are almost always the result of high-speed vehicular trauma. Because of the tremendous force required to produce this injury pattern, coexistent multisystem trauma is the rule.

When a femoral head fracture and hip dislocation coexist, patients assume the position typical for the dislocation. Hip mobility is markedly reduced, and pain usually is severe. After initial stabilization, the involved extremity should be examined carefully for associated fractures of the femoral shaft and knee. The neurovascular examination should assess for femoral or sciatic nerve injury. Radiographs should be evaluated carefully for any femoral head fracture in all patients with hip dislocations. Evidence for fracture of the femoral head can be subtle. These fractures can be detected on radiographs by following the curve of the dislocated head and the acetabular cup to search for a small fragment that could otherwise be overlooked. Known or suspected injuries can be further defined by CT or MRI.

In most cases, satisfactory results can be obtained with closed reduction (see Fig. 49.30B). Several experts recommend obtaining a CT scan of the hip before closed reduction to further define the injury and locate fracture fragments. If the hip cannot be reduced by manipulation or if reduction of the femoral head fragment is unsatisfactory, open reduction will be required.
Dislocation of Hip Prosthetics

An increasing number of patients have undergone hip arthroplasty. In addition to those procedures performed for treatment of femoral neck fractures, more than 230,000 patients undergo elective primary THA each year. Postoperative dislocation occurs in 0.5% to 3% of patients with primary THA and in 5% to 27% of patients with a revised THA. Although most dislocations take place within 3 months of surgery, “late dislocations” have been reported up to 10 years after the operative procedure; such dislocations result from major trauma or from trivial events (eg, rising from a seated position). Posterior dislocations account for 75% to 90% of cases (see Fig. 49.15). Reduction techniques for prosthetic hip dislocations are identical to those described earlier. Consultation with an orthopedic surgeon is essential for safe reduction and development of a long-term treatment plan for the patient. Reduction of the prosthesis does not carry the same urgency as for reduction of a dislocated native hip, because there is no risk for the development of AVN once the femoral head has been replaced. Traction on the sciatic nerve can occur, however, making early reduction more compelling. In addition, the reduction itself carries the unique dangers of loosening of the components, fracturing of the surrounding bone, and movement of the acetabular cup. Reduction is best performed either by or in consultation with an orthopedic specialist.

Soft Tissue Injuries

Soft tissues can be subject to muscle or tendon strain or contusions from misuse, overuse, or trauma. Rupture, hemorrhage, or myositis ossificans can develop in muscles.

Muscular Injuries

Strenuous exercise by a poorly conditioned person, sudden exertion, and direct trauma all can injure soft tissues. Cold temperature, vascular or infectious disease, fatigue, and poor training are predisposing conditions for muscular injury.

Classification of complete and partial tears is reasonable and of clinical utility. Partial tears are reversible injuries that are aggravated by movement or tension. Mild spasm, swelling, ecchymosis, and tenderness cause minor loss of function and strength. Complete tears produce a palpable depression, and the torn muscle edge is often palpable. Other possible findings include severe spasm, swelling, ecchymosis, tenderness, and loss of muscle function. In significant muscle strains, radiographs are needed to evaluate for the possibility of an accompanying bone avulsion injury.

Initial management of incomplete tears traditionally includes the local application of ice for the first 48 hours, followed by heat. Compressive wraps can exacerbate distal venous clot formation, and do not significantly decrease recovery time. A regimen of nonsteroidal anti-inflammatory agents to achieve sufficient analgesia is important for recovery and patient satisfaction. Muscle relaxants may be useful when the injury is accompanied by muscular spasm. In general, complete rest of the affected muscle should be maintained, with the recommendation of “weight bearing as tolerated.” This progressive muscle loading can be started within 3 to 5 days once sufficient scar has formed. To prevent reinjury, muscle loading should be limited by the patient’s pain. Any patient with significant injury should be referred for physical therapy.

A complete muscle tear is a serious condition. Consultation plus follow-up care with an orthopedic surgeon or sports medicine specialist is vital for these patients. Athletes commonly experience muscular injury from accidents and overtraining. The two most common injuries involve the hamstrings and the quadriceps.

The Hamstrings. Hamstring muscle strains are common in sports involving running and sudden acceleration. The injury is accompanied by sudden intense pain in the posterior aspect of the thigh. Any active or passive motion at the hip is poorly tolerated because of the intense pain that movement causes. Ischial avulsion fractures can occur, and pelvic radiographs should be obtained if the examination reveals bony tenderness. Crutches and toe-touch weight bearing are recommended until the patient is evaluated by a physician trained in sports medicine. Toe-touch weight bearing refers to walking with crutches while the toes of the injured extremity rest on the ground without placing any weight on it. Appropriate weight-training programs speed rehabilitation of this injury. Complete recovery from a hamstring muscle strain can take weeks to months.

The Quadriceps. The quadriceps is the most common muscular group to sustain complete tears. This injury occurs when the muscles are contracted suddenly against the body’s weight, as may occur when an athlete slips or stumbles and
Tendon Injuries

Clinically, tendon strains tend to have a more insidious onset than that typical for muscle strains. These strains occur at the attachment of the muscles to the superior or inferior pubic ramus, the pubic symphysis, the ischium, and the femur. One study found adductor strains to be the most common groin injury in athletes, with 62% of the cases involving the adductor longus muscle. The adductor magnus and brevis and the pectineus often are involved as well. This injury commonly occurs in skaters and cross-country skiers when an accidental stress abducts the thigh during a powerful contraction of the adductors. These muscles also can be injured from overuse in an unconditioned patient. Local pain is noted at the inferior pubic ramus and the ischial tuberosity. Extension, abduction, and adduction of the hip are painful. The pain might radiate to the back of the thigh.

Pain over the greater trochanter could represent tendon strain of the attachments of the gluteus medius, gluteus minimus, tensor fasciae latae, or piriformis. The pain is aggravated by resisted abduction. Tenderness in the groin and painful hip movement suggest a strain of the iliopectineal bursa. MRI will show marrow edema of the femoral neck.

Osteitis Pubis

Osteitis pubis is a poorly understood disorder. It is characterized by pubic symphysis pain and joint disruption and is most common in distance runners and soccer players. The adductor muscles act as a “compression strut,” displacing forces across the hip. The most likely mechanism is repetitive pulling of the adductor muscles, causing increased shearing at the pubic symphysis.

Clinically, patients have groin pain of insidious onset, with most reporting pain at the symphysis and adductor muscles. Pain usually can be elicited on palpation of the symphysis and also can be provoked by adduction of the hip or by sit-ups. Plain radiographs show widening of the symphysis, irregular contour of the articular surfaces, or periarticular sclerosis (a late finding) (Fig. 49.31). These features are not specific and in one study were seen in 76% of asymptomatic soccer players. MRI is the imaging study of choice and will show marrow edema on T2 images early in disease. Osteitis pubis has been associated with spontaneous cases of pubic symphysis osteomyelitis and should be considered in the differential diagnosis.

Vascular Injuries

Hip dislocations and femoral fractures may have associated arterial injury. The vessel can be partially lacerated, dissected, completely severed, or thrombosed. Lack of distal arterial flow might also represent a stretched vessel in spasm. The superficial femoral artery is most commonly injured with trauma to the hip and thigh. The common and the deep femoral arteries are less frequently injured. In the acute setting, penetrating trauma is the usual mechanism of injury. Arterial injury with a femoral shaft...
fracture is rare. Anterior and superior dislocations can produce femoral artery injury.

Neurologic Injuries

Peripheral nerve injury can be caused by trauma, infectious agents, and degenerative disease. In trauma, nerves can be injured by a blunt object that causes a contusion, by a sharp penetrating object that produces a partial or complete tear, or by stretch. Nerves are particularly vulnerable to prolonged ischemia, which can lead to necrosis. Compression of the nerve from a hematoma or a dislocated femoral head may also appear as a neurapraxia manifested by transient loss of conductivity. The femoral and sciatic nerves are rarely injured with femoral shaft fractures, because they are encased in muscle throughout the length of the thigh.

Treatment of neurovascular compromise from a hip dislocation or a displaced femoral fracture consists of immediate reduction to ensure limb viability. Whenever possible, reduction should be accomplished before the patient is transferred to another treatment center.

When the femoral nerve is injured, the iliac and femoral arteries are commonly involved because of their anatomic proximity. The femoral nerve is most often traumatized in penetrating trauma of the pelvis, groin, or thigh. Femoral neuropathy occasionally results from compression by a hematoma within the abdominal wall or the iliopsoas as a complication of hemophilia, anticoagulant therapy, or severe trauma.

The motor deficit in complete femoral neuropathy manifests as marked weakness of knee extension. The patient is able to walk on level ground yet has extreme difficulty walking up stairs or an incline. Patients cannot rise from a sitting position because of significant proximal muscle weakness. The sensory deficit varies but is localized along the anterior aspect of the thigh and medial lower aspect of the leg. The most reliable spot for testing for a sensory deficit is just superior and medial to the patella. The deep tendon reflex of the knee is diminished or absent with such deficits.

If traumatic neuropathy is suspected, immediate orthopedic consultation should be obtained. Nerve exploration and repair generally are preferred for penetrating trauma and when direct impingement on the nerve by bone fragments or hematoma is suspected. Surgical exploration and drainage of a hematoma that is impinging on the femoral nerve are appropriate.

Progressive nontraumatic neuropathies warrant urgent neurology consultation. With chronic neuropathy, atrophy of the anterior aspect of the thigh already has developed. The motor deficits were discussed previously.

Sciatic injury is rare with femur fractures, but occasionally it may be the result of traction used to stabilize the fracture during the initial management period. Complete traumatic injury can result from a deep penetrating wound in the hip, thigh, or buttock. Posterior hip dislocations and fracture-dislocations produce sciatic neurapraxia in 10% to 14% of patients with these injuries. Patients with complete sciatic neuropathy have paralysis of the hamstring muscles and all muscles below the knee. With partial injury, a peroneal palsy with weakness of the extensor hallucis longus muscle is the most sensitive clinical sign. There is sensory loss below the knee and along the posterior aspect of the thigh. The deep tendon reflex at the ankle is absent or diminished. Sciatic nerve palsy from inadvertent injection into the nerve or secondary to intraneural or extraneural hemorrhage in patients taking anticoagulants has been described.

Sciatic injury from posterior dislocations often consists of only transient loss of conductivity, particularly in motor fibers. Unfortunately, the other patterns of injury to the sciatic nerve carry the worst prognosis of all peripheral nerve injuries. The prognosis is poorest when the injury is proximal and complete. Even with optimal repair, recovery often is inadequate. Sciatic neuropathy is a disabling problem. Obvious atrophy of the lower part of the leg and foot develops, followed by ulceration of the sole of the foot and infection. A below-the-knee amputation frequently is necessary in these cases.

ACKNOWLEDGMENTS

We would like to thank Drs. Brittany Murray, James F. Fiechtl, and Robert W. Fitch for their work on this chapter in previous editions.

The manuscript was copyedited by Linda J. Kesselring, MS, ELS, the technical editor/writer in the Department of Emergency Medicine at the University of Maryland School of Medicine.

KEY CONCEPTS

- Hip dislocation is an orthopedic emergency. The likelihood of avascular necrosis (AVN) is related to both the initial degree of trauma and the amount of time the femoral head remains out of joint. Reduction of the hip within 6 hours after dislocation significantly decreases the incidence of AVN.
- When a painful hip makes ambulation difficult and plain radiographs do not reveal a fracture, computed tomography (CT) or magnetic resonance imaging (MRI) should be performed. MRI is the gold standard for diagnosis.
- In patients with intertrochanteric fractures, hemodynamic instability can result from dehydration and blood loss. Up to 70% of patients with these injuries are under-resuscitated.
- It is important to identify acetabular fractures before closed reduction is attempted, because intra-articular bone fragments can interfere with effective reduction.
- In elderly patients, the use of femoral nerve blocks should be considered due to the adverse effects of parenteral opioids.

The references for this chapter can be found online by accessing the accompanying Expert Consult website.
after the trauma. The ossific mass is often palpable and may limit persist past 10 to 14 days or if symptoms intensify several weeks a direct blow to muscle. It should be suspected when symptoms found. Traumatic myositis ossificans results most commonly from fractures ranges from 9.6% to 13.3%.

teric fractures have an associated mortality rate of 10% to 30% in the first year after a femoral neck (also known as an insufficiency fracture) fracture is 14%. Intertrochanteric fractures have an associated mortality rate of 10% to 30% in the first year. The reported mortality rate from subtrochanteric fractures ranges from 9.6% to 13.3%.

A 40-year-old man complains of persistent thigh pain that worsens over 2 weeks after an assault with a baseball bat. His pain is worse with knee extension. On physical examination, you note that there is a small palpable mass at the midanterior thigh. What should be your next confirmatory test?

A. Bone scan for fracture
B. Bone scan for stress fracture
C. Computed tomography (CT) scan for tumor
D. Magnetic resonance imaging (MRI) for evaluation of torn muscle
E. Radiograph for heterotropic calcification

Answer: E. Myositis ossificans (heterotrophic ossification) is pathologic bone formation at a site where bone is not normally found. Traumatic myositis ossificans results most commonly from a direct blow to muscle. It should be suspected when symptoms persist past 10 to 14 days or if symptoms intensify several weeks after the trauma. The ossific mass is often palpable and may limit motion, depending on its location.

An 80-year-old woman presents complaining of pain in her right leg after a motor vehicle collision (MVC). Emergency medical services (EMS) noted a swelling and a deformity to her thigh, so they placed a traction device on her leg. Her vital signs are: blood pressure, 80/40 mm Hg; heart rate, 110 beats per minute; and respiratory rate, 18 breaths per minute. What is the most appropriate next step in the management of the patient’s fracture?
A. Femoral nerve block and leave the traction device in place
B. Femoral nerve block and remove the traction device
C. Intravenous morphine and leave the traction device in place
D. Intravenous narcotic pain medication and remove the traction device
E. Immediate orthopedic consult to take the patient to the operating room for an open reduction and internal fixation (ORIF)

Answer: B. Although the patient may ultimately need to go to the operating room, the patient is currently unstable and requires resuscitation and evaluation for other injuries. A femoral nerve block is invaluable as an adjunct or alternative to systemic analgesics in a patient at risk for hypotension and has been underused by emergency clinicians. Prolonged traction during the assessment and management of other injuries can cause or worsen serious neurologic injury in the thigh by producing potentially damaging tension on the sciatic and/or femoral nerves.

What is the most common complication of a proximal femur fracture?
A. Avascular necrosis (AVN)
B. Myositis ossificans
C. Osteomyelitis
D. Pulmonary embolism
E. Septic arthritis

Answer: A. AVN is the most common complication of proximal femur fractures (despite optimal treatment) because of the complex arterial anatomy. Deep infection in the form of osteomyelitis or septic arthritis is more common with femoral neck fractures because the fracture line extends into the joint. Pulmonary embolism is another significant complication and is the leading cause of death 7 days after fracture in all orthopedic patients.

A 60-year-old woman presents complaining of right hip pain after a trip and fall at home. The patient denies loss of consciousness or other symptoms. You note that the patient’s right leg is internally rotated, and the thigh is adducted and flexed at the hip joint so that the ipsilateral knee is resting on the opposite thigh. Which is the correct maneuver?
A. Apply traction and splint the leg in full extension
B. Apply traction to an extended knee and flexed hip at 90 degrees with a gentle rotational component
C. Consult orthopedics immediately to take the patient to the operating room
D. Provide analgesia and Holter monitor for discharge when ambulatory
E. Use the Allis maneuver and place the patient in a knee immobilizer.
### Question 49.6

A mother brings her 11-year-old boy for evaluation of left knee pain that is worse after physical activity. Radiographs of the knee were negative. What is the most appropriate next step in the patient's management?

- A. Hip radiograph with frog-leg views
- B. Joint aspiration for evaluation of transient synovitis
- C. Place a knee immobilizer and ensure follow-up in 1 week
- D. Radiograph of right knee for comparison
- E. Rest, ice, compression, elevation, and orthopedic follow-up urgently

**Answer:** A. This patient may have a slipped capital femoral epiphysis (SCFE), which most commonly develops in boys 10 to 17 years old during their period of rapid growth. Referred pain to the knee is a classic manifestation, and patients frequently present with groin, thigh, or knee pain rather than hip pain. Initially, anteroposterior, lateral, and frog-leg lateral radiographs of the hip should be obtained. The frog-leg lateral projection shows the hip in a plane midway between the anteroposterior and lateral views.

### Question 49.7

A 75-year-old woman presents after a fall from standing. She has right hip pain and tenderness to palpation but no obvious deformity. Right knee and ankle examinations are normal, without tenderness, deformity, or external signs of trauma. Hip and pelvis radiographs are negative for fracture, but the patient is unable to bear weight on her right leg. The next appropriate step in management is:

- A. Admit to the hospital for bed rest.
- B. Discharge patient home with analgesia and a walker.
- C. Obtain magnetic resonance imaging (MRI) of the hip to assess for fracture not identified by radiographs.
- D. Obtain radiographs of the rest of her right leg to ensure no occult fracture is present.

**Answer:** C. With hip injury, if radiographs do not show a fracture or suggestion of injury and the patient is unable to ambulate, further imaging studies should be obtained to evaluate for occult fracture. Two percent to 10% of all hip fractures are radiographically occult. Failure to detect these fractures results in increased morbidity and mortality.

### Question 49.8

Which of the following injuries is appropriate for traction splinting by prehospital providers?

- A. Femoral fracture with bone protrusion through skin
- B. Posterior hip dislocation
- C. Severe crush injury of leg with obvious deformity of the knee
- D. Suspected closed mid shaft femoral fracture

**Answer:** D. Traction splints can provide pain relief, immobilization, and limit blood loss when applied correctly to a femoral fracture. However, contraindications to the use of traction splints include pelvic fractures, patellar fractures, ligamentous knee injuries, and tibia or fibula fractures. Traction in the prehospital setting should not be applied to any open fracture that has exposed bone. Such reduction pulls grossly contaminated bone fragments back into the wound before adequate debridement can be undertaken in the operating room.

### Question 49.9

A 15-year-old female gymnast presents after experiencing the sudden onset of severe groin pain during a dismount when she landed in a flexed hip position. The pain radiates into her abdomen, and flexion of the hip produces pain, but there is no deformity noted. What is the most likely radiographic finding?

- A. Avascular necrosis (AVN) of the femoral head noted on magnetic resonance imaging (MRI) scan
- B. Diastasis of the pubic symphysis on anteroposterior pelvis radiographs
- C. Femoral neck fracture on dedicated anteroposterior hip radiograph
- D. Iliopsoas muscle with some associated hemorrhage on computed tomography (CT) scan

**Answer:** A. Gymnasts and dancers are the group of athletes most likely to experience an injury to the iliopsoas as a result of sudden forceful hip flexion against resistance. Severe pain often is experienced in the groin, thigh, or low back region. Severe intra-abdominal pain is common at the muscle origin and may dominate the clinical picture. Examination reveals groin tenderness and pain with active hip flexion. Radiographs of the femur should be obtained to identify an avulsion fracture of the lesser trochanter. CT scan frequently will demonstrate a large hematoma. Bed rest with partial flexion at the knee and hip generally is required for 7 to 10 days. With severe strains, symptoms may persist for 2 to 3 months. Referral to a sports medicine specialist is appropriate.

### Question 49.10

A 45-year-old male presents with a posterior hip dislocation after a motor vehicle crash (MVC) noted on radiographs. After sedation of the patient and reduction of the dislocated hip, what is the most appropriate next step in the patient's management?

- A. Have the patient ambulate to assess the stability of the joint.
- B. Measure the femoral compartment pressure.
- C. Obtain postreduction hip radiographs to assess for additional injuries and adequate reduction.
- D. Place a traction splint.

**Answer:** C. Obtaining postreduction radiographs to ensure adequate reduction and evaluate for associated injuries is essential. After closed reduction, the hip should be tested for stability, which is accomplished by gently taking it through a full range of motion to see whether it will re-dislocate. After testing has ensured stability, the injured extremity should be placed in a knee immobilizer, and an abduction pillow should be applied to prevent repeat dislocation.
CHAPTER 50

Knee and Lower Leg

Daniel J. Pallin

KNEE

PRINCIPLES

Background and Importance

Knee injuries range in severity from minor contusions to limb-threatening injuries to the popliteal artery. The knee joins the longest mechanical levers in the body, the femur and tibia, and is therefore subject to high forces. It is the largest and most complex joint in the body and functions through a complicated interaction of flexion, extension, rotation, gliding, and rolling. Its large synovial space is frequently involved in infections and other inflammatory conditions.

The main goal in emergency evaluation of the traumatized knee is to prevent further damage by identifying reparable vascular injuries, reducing dislocations, stabilizing fractures, and administering antibiotics when indicated. Definitive treatment of less urgent problems is deferred to other settings, such as primary care offices for chronic knee pain and orthopedic clinics for ligamentous injuries.

ANATOMY AND PHYSIOLOGY

The knee is a modified hinge, diarthrodial synovial joint that consists of the tibiofemoral and patellofemoral joints. The head of the fibula, although not part of this articulation, is closely approximated laterally and provides a site for the attachment of muscles and ligaments. Joint stability is provided by ligaments, although surrounding muscles and the joint capsule contribute as well (Fig. 50.1).

The distal femur terminates in the medial and lateral condyles. A condyle is a rounded prominence at the end of a bone, where it interfaces with another bone. An epicondyle is a prominence on a condyle, where a ligament or tendon attaches. The femoral condyles protrude anteriorly, leaving a vertical groove between them, forming the femoral trochlea. Trochlea is the term for an anatomic structure that resembles a pulley. The patella slides up and down in the groove during knee extension and flexion.

The femoral condyles articulate with the superior surface of the tibia and tibial condyles. The medial and lateral menisci are cushions between the femoral and tibial condyles. The tibia is anchored to the femur by four strong ligaments, the anterior and posterior cruciate ligaments (ACL and PCL) and medial and lateral collateral ligaments (MCL and LCL). The ACL and PCL are located deep within the knee. The ACL arises from the posterior aspect of the femoral intercondylar notch and inserts on the anterior surface of the tibial plateau within the tibial intercondylar notch. It prevents anterior displacement of the tibia relative to the femur. The PCL arises from the anterior aspect of the femoral intercondylar notch and inserts on the posterior surface of the tibial plateau within the tibial intercondylar notch. It prevents posterior displacement of the tibia relative to the femur. The cruciate ligaments have a rich blood supply, and injury typically results in a hemorrhagic knee effusion.

The MCL and LCL connect the femoral epicondyles to the tibial condyle and head of the fibula, respectively. The MCL prevents valgus deviation. Valgus deviation refers to angulation with the apex pointing medially. The LCL prevents varus deviation, angulation of the tibia relative to the femur with the apex pointing laterally.

Functionally, the knee joint can be divided into three compartments—patellofemoral, medial tibiofemoral, and lateral tibiofemoral. These compartments, defined anatomically by the articulation of the bones, are contained within the same joint capsule. The patellofemoral compartment, located anteriorly, contains the quadriceps tendon, which envelops the patella, continues inferiorly as the patellar tendon, and inserts on the tibial tubercle. The fibers of the medial and lateral retinacula are found on either side of the patella, originating from the vastus medialis and vastus lateralis. The patella increases the mechanical advantage of the quadriceps tendon. The quadriceps tendon is a continuation of the quadriceps femoris muscle, which consists of the rectus femoris, vastus medialis, vastus lateralis, and vastus intermedius, which extend the knee.

The medial tibiofemoral compartment is located on the medial aspect of the knee and consists of the medial femoral condyle, concave medial tibial condyle (plateau), medial meniscus, MCL, adductor tubercle, and pes anserinus. The pes anserinus (literally, goose foot) is a three-pronged tendinous structure that is the conjoined insertion of the sartorius, semitendinosus, and gracilis muscles, located on the proximal medial tibia.

The lateral tibiofemoral compartment encompasses the lateral half of the knee joint and includes the lateral femoral condyle and epicondyle, lateral tibial condyle (plateau), LCL, lateral meniscus, and popliteus tendon. The fibular head can be palpated posterolaterally and inferiorly to the joint line but is not usually considered a structure of the lateral tibiofemoral compartment. The fabella, present in some patients, is a sesamoid bone located in the lateral head of the gastrocnemius muscle and should not be mistaken for an intraarticular loose body or fracture fragment. The knee is surrounded by a thick ligamentous sheath composed largely of tendons and their expansions. The capsule of the knee joint is reinforced at multiple sites—anteriorly, by the ligamentum patellae; medially and laterally, by the medial and lateral patellar retinacula; and posterolaterally, by a combination of structures termed the posterolateral corner. The tibiofemoral joint communicates with the suprapatellar bursa, which expands in conditions that cause knee effusion. The prepatellar bursa is anterior to the patella and does not communicate with the tibiofemoral joint. It is important not to confuse prepatellar bursitis with knee arthritis.

The popliteal fossa is a hollow in the posterior aspect of the knee. It is bounded laterally by the biceps femoris tendon, medially by the semimembranosus and semitendinosus muscles, and inferiorly by the two heads of the gastrocnemius muscle. Found within the popliteal space are the popliteal artery, popliteal vein, and peroneal and tibial nerves.

The popliteal artery is the continuation of the femoral artery beyond the adductor hiatus. It descends across the posterior...
Posterior explains the high incidence of arterial injury with knee dislocation for disruption of the joint capsule, with expulsion of synovial fluid and blood into the thigh or lower leg. Lower energy injuries are more commonly associated with meniscal tears, patella dislocations, and less severe ligament injuries. Activities with twisting and turning are associated with anterior cruciate and meniscal tears. Immediate deformity, hemarthrosis, or instability suggests an intraarticular fracture, cruciate ligament injury, or vascular injury. By contrast, a torn meniscus more commonly is associated with delayed onset of swelling over 12 to 24 hours, intermittent locking associated with joint line pain, and eventually arthritis and recurrent effusion later in life.

Locking of the knee manifests clinically with inability to extend the joint fully. It typically results from a meniscal tear or trapping of a loose body within the joint, thereby preventing full extension. A complaint of giving way may indicate instability or involuntary muscle inhibition secondary to pain. This is a nonspecific symptom and may be reported in association with arthritis or patellofemoral disorders when inhibition of quadriceps function occurs in association with episodic pain. Although pain remains a helpful indicator of injury, its absence should not be interpreted as proof that only minor injury is present. Complete ligament tears may be less painful than partial tears because the completely disrupted ligament has no tension across injured fibers.

Physical Examination

Proper examination of the knee requires the patient to be supine, with both legs exposed. The question of whether knee pain may be the result of hip or spine pathology should be raised early, and the neurovascular integrity of the foot should be assessed. Examination of the knee begins with visual inspection (Box 50.1), followed by palpation (Fig. 50.2). Any obvious deformity, swelling, effusion, or ecchymosis is noted. Localized swelling should be distinguished from the presence of a joint effusion, which may obliterate the normal contour of the knee. If a large effusion is present, the patella is elevated from the femur by fluid, and the patella can be ballotted against the femur. Loss of the medial peripatellar concavity may be the only sign of a small knee effusion. An effusion in the prepatellar bursa is found just beneath the skin anterior to the patella; this should not be confused with a knee effusion.

Palpate areas of suspected tenderness last to avoid causing anxiety and muscle spasm during the examination. The insertion of the patellar tendon onto the tibial tubercle should be palpated.

**CLINICAL FEATURES**

Patients with knee injuries may have pain, tenderness, deformity, limited range of motion (ROM), effusion, warmth, or redness. Knee pain without an immediately apparent knee abnormality should prompt a careful evaluation of the entire femur and hip, injuries of which frequently manifest with pain referred to the knee. Patients with radiculopathy of the third, fourth, or fifth lumbar roots also may report knee pain. Children with a slipped capital femoral epiphysis, toxic tenosynovitis, or septic hip frequently complain of knee pain.

A knee effusion may result from infection, hemarthrosis, lipohemarthrosis, or inflammatory arthritis. Arthrocentesis may be used for diagnosis when the mechanism is not clear and there is suspicion of infection.

High-energy trauma without knee swelling should raise suspicion for disruption of the joint capsule, with expulsion of synovial fluid and blood into the thigh or lower leg. Lower energy injuries are more commonly associated with meniscal tears, patella dislocations, and less severe ligament injuries. Activities with twisting and turning are associated with anterior cruciate and meniscal tears. Immediate deformity, hemarthrosis, or instability suggests an intraarticular fracture, cruciate ligament injury, or vascular injury. By contrast, a torn meniscus more commonly is associated with delayed onset of swelling over 12 to 24 hours, intermittent locking associated with joint line pain, and eventually arthritis and recurrent effusion later in life.

Locking of the knee manifests clinically with inability to extend the joint fully. It typically results from a meniscal tear or trapping of a loose body within the joint, thereby preventing full extension. A complaint of giving way may indicate instability or involuntary muscle inhibition secondary to pain. This is a nonspecific symptom and may be reported in association with arthritis or patellofemoral disorders when inhibition of quadriceps function occurs in association with episodic pain. Although pain remains a helpful indicator of injury, its absence should not be interpreted as proof that only minor injury is present. Complete ligament tears may be less painful than partial tears because the completely disrupted ligament has no tension across injured fibers.

**Physical Examination**

Proper examination of the knee requires the patient to be supine, with both legs exposed. The question of whether knee pain may be the result of hip or spine pathology should be raised early, and the neurovascular integrity of the foot should be assessed. Examination of the knee begins with visual inspection (Box 50.1), followed by palpation (Fig. 50.2). Any obvious deformity, swelling, effusion, or ecchymosis is noted. Localized swelling should be distinguished from the presence of a joint effusion, which may obliterate the normal contour of the knee. If a large effusion is present, the patella is elevated from the femur by fluid, and the patella can be ballotted against the femur. Loss of the medial peripatellar concavity may be the only sign of a small knee effusion. An effusion in the prepatellar bursa is found just beneath the skin anterior to the patella; this should not be confused with a knee effusion.

Palpate areas of suspected tenderness last to avoid causing anxiety and muscle spasm during the examination. The insertion of the patellar tendon onto the tibial tubercle should be palpated.

**Fig. 50.1.** Posterior and anterior views of the right knee.
Box 50.1
Examination of the Knee

1. Assess neurovascular integrity of the foot.
2. Determine whether a knee effusion is present, and assess for gross deformity.
3. Identify signs of infection—redness, warmth, and effusion out of proportion to mechanism of injury.
4. Localize tenderness.
5. Assess range of motion and perform stability testing and meniscal evaluation when feasible.

Fig. 50.2. Sites for palpation of tenderness in the knee. 1, Quadriceps tendinitis; 2, prepatellar bursitis, patella pain; 3, retinacular pain after patella subluxation; 4, patella tendinitis; 5, fat pad tenderness; 6, tibial tubercle pain caused by Osgood-Schlatter disease; 7, meniscus pain; 8, collateral ligament pain; 9, pes anserine tendinitis-bursitis. (Adapted from Cailliet R: Knee pain. In soft tissue pain and disability, ed 3, Philadelphia, 1976, FA Davis, p 411.)

Pain at this location in an adolescent is the hallmark of Osgood-Schlatter disease. In an adolescent, pain along the femoral or tibial epiphysis after trauma may represent a Salter-Harris type I fracture (ie, a nondisplaced fracture through the physis). The joint line should be palpated carefully. Pain along the joint line may also indicate meniscal pathology. The posterior aspect of the knee should be examined for fullness, which may indicate a Baker’s cyst or popliteal artery pseudoaneurysm.

Accurate diagnosis of soft tissue knee injuries often is impossible in the acute phase because of pain and swelling. In the acute setting, the main goals are to relieve pain, stabilize the joint, rule out vascular injury, determine the need for radiography, and identify infections and inflammatory conditions hidden by a history of minor trauma. Loss of active extension of the knee and inability to maintain the passively extended knee against gravity are the hallmarks of quadriceps and patellar tendon rupture, which otherwise may be clinically occult.

A number of maneuvers have been developed to aid the emergency clinician in diagnosing ligamentous and meniscal injuries using only the physical examination. However, interpretation of these maneuvers is limited by pain, splinting, or effusion so they are not particularly useful in the acute injury phase and have been found variably accurate, at best, when compared with magnetic resonance imaging (MRI) or arthroscopy findings. Accuracy of the findings of these maneuvers likely is improved if they are used after pain and swelling have resolved. The primary initial goals in emergency care are to identify whether fracture or vascular injury is present, ensure necessary nonweightbearing or decreased weightbearing, and refer for reevaluation by a primary care provider or orthopedist. With this caveat, we present a brief overview of the more common stability tests.

Tests for Specific Injuries and Disturbances

Anterior Drawer Test. The anterior drawer test seeks to identify tears of the ACL. A positive test result is defined as greater anterior movement of the tibia as compared with the other knee. The test is performed with the patient in a supine position, hip flexed at 45 degrees, and knee flexed at 90 degrees. The test is poorly sensitive but fairly specific. Lachman’s test is a more accurate way to diagnose ACL injuries, with a sensitivity of 80% when performed acutely and 100% when performed with the patient under general anesthesia. Lachman’s test is done with the knee flexed 20 to 30 degrees while the examiner uses one hand to grasp the thigh and stabilize it. The tibia is pulled anteriorly, and the examiner notes tibial excursion. The examiner records “firmness” or a “soft endpoint.” The endpoint can be graded as 1+ (0–5 mm more displacement than on the normal side), 2+ (5–10 mm), or 3+ (>10 mm). The PCL must be intact for the test results to be valid. Arthrometers are devices that quantitate anterior displacement of the tibia relative to the femur and are far more accurate in diagnosing ACL tears than the anterior drawer and Lachman’s tests, although these devices are rarely used in the ED setting.

The pivot shift test, also termed subluxation provocation or the jerk test, is performed to detect anterolateral rotatory instability associated with an injury to the ACL or lateral capsular structure. This sensitive but nonspecific test should be done carefully, if at all, in the acutely injured knee because the test maneuvers can exacerbate the initial injury.

The pivot shift test is performed with the patient supine. The knee is examined in full extension. The tibia is internally rotated by the examiner’s thigh. A smooth backward force is applied to the foot while the examiner applies tension to the other knee. The tibia subluxates when the knee is extended and relocates when it is flexed to 20 to 30 degrees. Grading of the relocation event is as follows: absent (0), rolling (1+), moderate (2+), or momentary locking (3+). Because of pain or spasm, the pivot shift test is unreliable without the use of anesthesia.

Posterior Drawer Test. The posterior drawer test assesses for PCL injury. The posterior drawer test can be accomplished with the patient’s knee flexed at 90 degrees and the foot stabilized by the examiner’s thigh. A smooth backward force is applied to the tibia. Posterior displacement of the tibia more than 5 mm, or a soft endpoint, indicates injury to the PCL. A normal knee should exhibit no significant posterior excursion. The posterior drawer test result may be positive in only 85% of patients with PCL insufficiency documented operatively.

Posterior Sag Sign Test. The posterior sag sign test is a second method of determining PCL integrity. Sensitivity in the acute phase is 79%. The test is done as follows. The patient is placed in a supine position, and a pillow is placed under the distal thigh for support while the heel rests on the stretcher. The knee
is flexed to 45 or 90 degrees, depending on which position provides the greater muscle relaxation. If the tibia sags backward, the test result is considered to be positive, indicating PCL insufficiency. If the posterior sag sign is not appreciated before the different drawer tests are performed, a false-positive result on the anterior drawer test is misinterpreted as an ACL injury. Posterior sag also may be shown by passive elevation of the leg in a fully extended position, with the examiner applying the elevating force at the ankle. As the leg is elevated, the tibia may fall back on the femur if the PCL is ruptured.

**Collateral Ligament Stress Test.** The collateral ligament stress test is used to test the integrity of the MCL and LCL. With the patient lying supine, the examiner applies varus and valgus stress with the knee at 0 and 30 degrees of flexion. Joint line opening is the amount of movement (ie, hinging) produced between the tibia and femur; this can be palpated and estimated in millimeters. The normal knee should be subjected to the same amount of varus and valgus stress; the joint line opening is then compared with that in the injured knee. Isolated collateral ligament tears are detected only with the knee in slight flexion because, in extension, the cruciate ligaments, capsule, and lesser ligaments of the knee provide significant lateral stability. Laxity in full extension implies complete collateral ligament tear and also injury to the cruciate ligaments or other structures. Laxity may be graded as grade I, some laxity, grade II, marked laxity, and grade III, total laxity.

**Assessing for Meniscal Tears.** Meniscal tears are difficult to diagnose in the acute setting; these assessments are best reserved for the convalescent phase. Even then, small meniscal tears can cause significant symptoms but may not be detected on physical examination, and arthroscopic evaluation may be required for diagnosis.

**Mcmurray’s Test.** McMurray’s test is used to help identify meniscal tears. The patient is placed in a supine position with the knee hyperflexed. The examiner grasps the foot with one hand and the knee with the other. The examiner flexes and extends the knee while simultaneously internally and externally rotating the tibia on the femur and providing slight varus and valgus stress. A positive test result is the occurrence of clicking palpable along the joint line, or locking of the knee.

**Apley’s Test.** This test also aids in diagnosing meniscal tears. With the patient prone, the knee is flexed 90 degrees, and the leg is externally rotated with pressure applied to the heel. Pain elicited by downward pressure suggests meniscal pathology. The pain should be relieved with distraction of the knee and rotation of the leg back to a neutral position. Although relatively specific, Apley’s test is not sensitive.

**DIAGNOSTIC TESTING**

**Radiologic Evaluation**

Because the sensitivity of radiographs for acute knee injuries is approximately 50%, we recommend computed tomography (CT) or knee immobilization and orthopedic referral for reevaluation when fracture is suspected and plain films are negative. MRI is slightly more sensitive than CT for fracture and is the imaging gold standard (comparable to arthroscopy findings) for soft tissue injury, but is rarely indicated in the evaluation of knee and leg trauma in the emergency department (ED).

Plain films are useful for diagnosing fracture, effusion, foreign bodies and, to a limited extent, joint space narrowing and lipohemarthrosis. Any disruption of the continuous line of the cortex should raise suspicion for fracture. Subtle cortical disruptions indicate nondisplaced fractures or draining cortical veins. The next step is to evaluate for the presence of an effusion, seen as a radiolucent area (with density similar to that of fat) distending the joint capsule. The presence of a linear interface between two different densities within an effusion suggests lipohemarthrosis (Fig. 50.3), in which the effusion contains not only blood but also fat. This feature results from the entry of marrow fat into the joint cavity and is diagnostic of fracture.

Clinical decision rules help decrease unnecessary radiography. According to the Ottawa Knee Rule, radiography is necessary only if any one of five conditions is present: (1) age older than 55 years; (2) inability to transfer weight from one foot to the next four times at the time of injury and in the ED; (3) inability to flex the knee to 90 degrees; (4) patellar tenderness with no other bone tenderness; and (5) tenderness of the fibular head. This rule detects nearly 100% of fractures while allowing significantly fewer radiographs to be done. The Pittsburgh Knee Rule states that radiography is necessary only if the patient fell or sustained blunt trauma to the knee and if either of two conditions is present: (1) age younger than 12 or older than 50 years; and (2) inability to walk four full weight-bearing steps in the ED. This decision rule

![Fig. 50.3. Lipohemarthrosis. A, Lateral plain film of the knee of a young woman with a nondisplaced patella fracture. The only radiographic abnormality is an effusion that contains a linear interface (arrow) between two soft tissue densities, suggesting lipohemarthrosis. B, MRI scan from the same patient shows plainly the presence of blood and fat in the effusion (arrow). The nondisplaced patella fracture is not seen.](image-url)
has been validated for use in children older than 5 years, with similar sensitivity to the Ottawa Rule.

When the two rules are compared, both have a sensitivity over 95%, but the Ottawa rule may be more specific, allowing fewer radiographs to be done without sacrificing sensitivity. We recommend use of a decision rule—the Ottawa or Pittsburgh Rule—as decision support when considering plain knee radiographs. Either rule may be adopted as a clinical decision rule and, if applied to all patients, will miss fewer than 1% of significant fractures. Regardless of which rule is applied, the patient should be reevaluated at follow-up for persistent or progressive symptoms.

Tunnel views, which image the intercondylar notch, are used to detect tibial spine fractures and loose bodies within the notch. Although most ligamentous injuries cannot be diagnosed by plain radiography, avulsion of the attachment site can be seen occasionally and provides indirect evidence of ligament disruption.

CT is most useful for detecting and classifying tibial plateau fractures and usually is done when the diagnosis is unclear or if operative intervention is being considered. CT angiography (CTA), which does not require arterial puncture. False-positive results can lead to unnecessary surgical exploration. From a practical standpoint, the patient must be moved from the ED to a radiology suite, where other injuries cannot be addressed, and the angiography team must be mobilized, often resulting in delays in care.

**Angiography**

In the ED evaluation of trauma to the knee and leg, angiography is indicated for evaluation of popliteal artery injury after knee dislocation. Conventional angiography, with its complication rate of about 2%, largely has been supplanted by CTA, which does not require arterial puncture. False-positive results can lead to unnecessary surgical exploration. From a practical standpoint, the patient must be moved from the ED to a radiology suite, where other injuries cannot be addressed, and the angiography team must be mobilized, often resulting in delays in care.

**Duplex Ultrasonography**

Duplex ultrasonography refers to the combination of two-dimensional ultrasound imaging plus color Doppler examination. This method is used for evaluation of the popliteal artery after tibiofemoral dislocation (discussed later). Color Doppler imaging is used to compare the velocity of blood in a narrowed area with the velocity just proximal to the narrowed area. As the lumen narrows, flow accelerates, and the ratio of velocities is an accurate predictor of the degree of stenosis.

**Radionuclide Bone Scan**

Almost never indicated as an emergency study, a radionuclide bone scan can be used to detect osteomyelitis or occult bony injuries, such as stress fractures, osteochondritis dissecans, and avascular necrosis. It is generally used only for patients who cannot undergo MRI or have ambiguous MRI results.

**Arthroscopy**

Arthroscopy of the knee is the most commonly performed orthopedic surgical procedure in the United States. This nonemergent procedure is useful in the diagnosis and treatment of knee injuries, including injuries of the meniscus, cruciate ligaments, articular cartilage, capsule, and synovium. Arthroscopy is superior to MRI for the diagnosis of meniscal tears and other soft tissue injuries, and the diagnosed problem can be repaired immediately. The need for arthroscopy is established in the convalescent phase of injury and need not be determined in the emergent setting as long as appropriate referral to an orthopedist is made.

**Joint Injection**

An open joint is considered a surgical emergency. When violation of the joint capsule is suspected but not obvious, 200 mL of sterile normal saline can be injected into the joint capsule and the laceration observed to see if the saline emerges from the laceration. Methylene blue had been used in the past but should not be used because it has not been shown to be more accurate, can interfere with arthroscopy, and may cause an inflammatory reaction.

**Arthrocentesis**

Aspiration of fluid from the knee joint can be diagnostic as well as therapeutic by reducing pressure from an effusion. Arthrocentesis should be performed if the injured knee is greatly distended with a tight effusion or when the cause of the joint effusion is unknown. Aspiration of the joint and subsequent analysis can differentiate simple effusion, hemorrhathrosis, lipohemarthrosis, and septic arthritis and often provides significant relief of pain for the patient.

**KNEE INJURIES**

**Dislocation**

**Anatomy and Pathophysiology**

Knee dislocation refers to tibiofemoral dislocation and should not be confused with patellofemoral dislocation, a relatively minor injury. Knee dislocation is a limb-threatening emergency because a popliteal artery injury occurs frequently. Knee dislocation is uncommon but should be considered in the setting of an appropriate injury mechanism because 50% of all knee dislocations are reduced spontaneously before the patient arrives at the ED. Reduction before ED arrival does not lessen the likelihood of vascular injury, however, and these patients should be evaluated for vascular injury, particularly when associated with ligamentous injuries and high-energy mechanisms.

By definition, knee dislocations are associated with significant ligamentous injury. The joint capsule is disrupted, with accompanying trauma to the muscles and tendons. Injury to the popliteal artery is the most severe complication and is the primary cause of morbidity and limb loss.

The neurovascular bundle, which is composed of the popliteal artery, popliteal vein, and common peroneal nerve, runs posteriorly behind all bony and ligamentous structures in the popliteal fossa. The popliteal artery is fixed in the fibrous tunnel of the adductor magnus hiatus proximally and traverses the fibrous arch of the soleus and interosseous membrane distally. In essence, it is tethered to the femur and tibia, and its inherent immobility renders it susceptible to injury during dislocation. Because of the parallel course of the popliteal vein and peroneal nerve, these are often injured simultaneously.

Anatomically, dislocations are described according to the displacement of the tibia relative to the femur. They are classified into five types—anterior, posterior, medial, lateral, and rotary. More than half of all dislocations are anterior and result from hyperextension. Posterior dislocations are the second most common type and usually result from high-velocity direct trauma to the flexed knee, often in association with vehicular trauma (eg, dashboard impact).

**Clinical Features and Differential Diagnosis**

The diagnosis of knee dislocation is based on the mechanism of injury and clinical and radiographic findings. When a dislocation is present and has not reduced spontaneously, it is usually obvious.
However, there may be no effusion after reduction because the ruptured capsule allows blood and joint fluid to escape into the thigh and leg.

Popliteal artery injury is reported in up to two-thirds of these patients. The collateral geniculate arteries around the knee also may be damaged directly or may be secondarily compressed by hematoma formation after the dislocation. Direct arterial injury, decreased collateral circulation, and elevated compartment pressures all may compromise limb perfusion. In addition to being clinically occult, vascular injury in blunt trauma is more difficult to manage because of associated soft tissue injury and edema.

Findings associated with peripheral vascular injury and management approaches are described in Chapter 41. The posterior tibial and dorsal pedal pulses should be evaluated, but popliteal artery injury may still be present in up to 15% of patients with these pulses present.

Isolated intimal tears are usually managed without surgery, but a vascular surgeon should be consulted when such a tear is identified. Isolated intimal tears are not detectable on physical examination and are seen only angiographically or with duplex ultrasonography. These injuries are treated nonoperatively with observation, with or without anticoagulation. Injuries to small branches of the popliteal artery can be managed by observation and serial examinations, and all such examinations must also include evaluation for possible development of compartment syndrome.

As with all limb injuries, neurologic integrity should be assessed and documented. The peroneal is the most commonly injured nerve with knee dislocation; some degree of dysfunction occurs in 20% to 40% of patients and is permanent in approximately 80% of them. Peroneal nerve function is evaluated by determining sensation of the dorsum of the foot and by having the patient dorsiflex the ankle. Less commonly, the posterior tibial nerve may be injured, which causes diminished plantar sensation and flexion of the foot. Complete nerve palsy in the acute setting is associated with a poor prognosis for recovery.

Diagnostic Testing

The diagnostic evaluation begins with an understanding of two crucial facts. First, half of all tibiofemoral dislocations are reduced before presentation, and injury to the popliteal artery should be assumed with tibiofemoral dislocation regardless, of spontaneous reduction. Therefore, the diagnostic strategy is applied to all patients with known knee dislocation, multiligament knee injury, or known or possible high-force trauma to the knee. The intubated multitrauma patient with ecchymosis around the knee may also harbor an occult popliteal injury.

Popliteal artery injury is assessed by measurement of the ankle-brachial index (ABI) with serial physical examinations, CTA, and duplex ultrasonography. Formal angiography is rarely used.

Serial physical examinations—palpation of the pedal pulses—is not sufficiently sensitive for an injury with such potentially devastating consequences. Adding measurement of the ABI improves sensitivity. The ABI is the ratio of the systolic blood pressure measured in the standard humeral location to the systolic pressure measured at the ankle. An ABI more than 0.9 has a negative predictive value for popliteal artery injury; approaching 100% in knee dislocation. Duplex ultrasonography and CTA are highly reliable options for diagnosis in this setting.

The choice of diagnostic strategy depends on the patient’s presentation. At one extreme is the patient with obviously impaired leg perfusion. In this case, emergency angiography or surgical exploration are indicated. At the other extreme is the patient with knee trauma but no clear indication that a dislocation even occurred. Fig. 50.4 depicts a safe and efficient algorithm.

During the secondary survey, the dislocation is reduced, if present on presentation. The feet are examined and, if both are warm and well-perfused, dorsalis pedis and posterior tibial pulses are palpable and symmetric and, in the awake patient, sensation is intact, the ABI can be determined. If the ABI is above 0.9, the physical examination, including ABI determination, is repeated every 3 to 4 hours for 24 hours. If no abnormalities attributable to popliteal artery disruption are detected, no further emergent evaluation is indicated. Before surgery to repair associated injuries, the surgeon may choose to perform duplex ultrasonography to evaluate for an isolated intimal tear, which, although not important to detect in the ED setting, can lead to complications during surgery. If the pedal pulses are asymmetric or the ABI is below 0.9, urgent CTA is indicated. If pedal pulses are absent, the foot is cool or otherwise appears poorly perfused, or there is an expansile popliteal hematoma, immediate surgical exploration is indicated, with or without arteriography.

Management

The dislocated knee should be reduced at the earliest opportunity if isolated and during the secondary survey if the patient is multiply injured. Unless there is diagnostic uncertainty, reduction should occur prior to obtaining imaging, with the neurovascular status documented before and after reduction. For patients being transferred from a nontrauma to trauma center, reduction should be attempted prior to transfer. Reduction usually can be accomplished with simple traction-countertraction, almost always requiring procedural sedation. Lateral pressure may be required—for example, for an anterior dislocation, the femur can be pushed posteriorly while the tibia is pulled anteriorly, with special care taken not to apply undue pressure to the popliteal fossa. Postero-lateral dislocations may not be reducible because the medial femoral condyle and MCL secure the dislocated joint in place, in which case emergent open reduction in the operating room is indicated. Because many reductions are unstable, the limb should be immobilized in a long leg posterior splint with the knee in 15 to 20 degrees of flexion, and popliteal artery injury sought, according to the algorithm shown in Fig. 50.4.

Disability is minimized by expedient revascularization and primary arterial repair, heparinization when not contraindicated, repair of popliteal venous injury, and thorough wound debridement. Open joints require prophylactic antibiotics, such as ceftazolin, 2 g IV qid. If the neurovascular structures remain intact after dislocation, the knee joint is reduced and allowed to rest for 2 to 3 days before reconstruction of the torn ligaments is considered.

Delayed complications associated with traumatic knee dislocations include deep vein thrombosis, compartment syndrome, pseudoaneurysm, and arterial thrombosis. Compartment syndrome generally develops within 24 to 48 hours of the initial injury. Pseudoaneurysms are rare but may form several hours to months after popliteal artery injury. Heterotopic ossification is a poorly understood syndrome of calcification of the soft tissues of the knee. It has been observed in uninjured knees of patients who have sustained major trauma. In its most severe form, heterotopic ossification can cause dramatic decrease in knee mobility. Almost half of dislocated knees are found to have subsequent heterotopic ossification, although the most function-limiting form may be limited to patients with a history of severe trauma.

Distal Femur Fractures

Anatomy and Pathophysiology

Distal femur fractures are uncommon, constituting approximately 4% of femur fractures. Fractures of the distal femur are essentially knee injuries. See Chapter 49 for more detailed discussion of femoral shaft and proximal femur fractures. A high-energy mechanism of injury is required. An isolated fracture of the
femoral condyle may occur, or the fracture may extend in a T or Y pattern to include the intercondylar or supracondylar region of the femur. Condylar fractures are intraarticular and may result in disruption of the articular surface, with subsequent arthritis.

Clinical Features

Patients with condylar or intercondylar fractures have pain and swelling in the distal femur and suprapatellar region and often are unable to bear weight. Examination may reveal shortening, rotation, and angulation of the extremity and tenderness to palpation along the medial or lateral joint line. Acute hemothrosis is common and may be caused by intraarticular extension of the fracture or associated ligamentous injury. Distal neurovascular status should be documented. Any laceration in the region of the fracture represents an open fracture until proven otherwise.

Diagnostic Testing

Routine anteroposterior (AP) and lateral views should be obtained and usually show the fracture pattern and any significant displacement of fragments. In high-energy injuries, radiographs of the ipsilateral hip and tibia are required to exclude associated fractures. Occasionally, CT or MRI may be required to diagnose a nondisplaced fracture. If signs of vascular impairment are present, consultation for angiography or surgical exploration should be obtained emergently.

Management and Disposition

Femur fractures are painful, and IV opioid analgesia is indicated, titrated to pain relief. Ultrasound-guided femoral nerve blocks are also extremely effective. After the initial examination, the leg should be splinted to prevent excessive motion of the fracture site, which also is helpful in reducing pain. Emergent orthopedic consultation is advised. In a stable patient with an uncomplicated fracture, reduction may be done with skeletal traction, followed by immobilization. Intraarticular fractures generally are treated with open reduction and internal fixation. Distal femur fractures may be associated with thrombophlebitis, fat embolus syndrome, delayed union or malunion if reduction is incomplete or not maintained, intraarticular or quadriceps adhesions if the fracture is intraarticular, angulation deformities, and osteoarthritis, particularly affecting the patellofemoral articulation. Virtually all patients with distal femur fracture require admission to an inpatient orthopedic service.

Tibial Plateau Fractures

Anatomy and Pathophysiology

The proximal end of the tibia is expanded into the medial and lateral condyles. Together they make up approximately three-quarters of the proximal tibial surface, and their integrity is important for normal knee alignment, stability, and motion. The plateau normally slopes 10 degrees from anterior to posterior; on a straight AP view, the anterior and posterior portions of the plateau may not appear to be at the same level.

Tibial plateau fractures often are intraarticular. The forces that normally act on the tibial condyles include axial compression and rotation. The most common mechanism of injury is a strong valgus force with axial loading. Severe high-energy tibial plateau fractures occur primarily in younger patients and are often the result of motor vehicle collisions (MVCs) or falls from heights.

![Algorithm for the management of knee dislocation](image-url)
These fractures occur in concert with many other injuries and may be open. Fatigue stress fractures of the tibial plateau occur mostly in older adults. These low-energy fractures are the result of compression forces in osteoporotic bones.

The Segond fracture represents a bone avulsion of the lateral tibial plateau (Fig. 50.5). The avulsion occurs at the site of attachment of the lateral capsular ligament. On radiographs, an oval-shaped fragment can be seen adjacent to the lateral tibial plateau, which can be confused with an avulsion from the adjacent fibular styloid. Segond fractures are usually accompanied by ACL disruption and anterolateral rotatory instability. Most Segond fractures are caused by sports injuries; the mechanism is almost always knee flexion with excessive internal rotation and varus stress.

**Clinical Features**

Knee fractures cause pain, tenderness, ecchymosis, soft tissue swelling, and hemarthrosis when intraarticular. A valgus or varus limb deformity may be present and usually indicates a depressed fracture or concomitant leg fracture. The most important aspect of the initial examination is assessment of neurovascular status. Many tibial plateau fractures cause vascular complications. The popliteal artery may be injured by fragments from bicondylar or comminuted fractures involving the subcondylar area. Displaced fractures of the lateral condyle may produce peroneal nerve paralysis in addition to injury to the anterior tibial artery. Stretch of the peroneal nerve is the usual cause of injury.

Soft tissue injuries also may involve the capsuloligamentous structures of the knee. Ligamentous injuries accompany tibial plateau fractures in up to 66% of cases, most often involving the ACL and MCL.

**Diagnostic Testing**

Lipohemarthrosis, seen as a fat-fluid level on a plain film, suggests an occult fracture and is caused by entry of marrow fat into the joint space (see Fig. 50.3). Lipohemarthrosis also is detected when fat globules are found on aspiration of a hemarthrosis. All knee radiographs should be examined closely for bone avulsion fragments from the fibular head, femoral condyles, and intercondylar eminence because these may indicate ligamentous injury. Widened joint spaces associated with a fracture of the opposite condyle also may indicate concomitant ligamentous injury.

CT and MRI are more sensitive than plain radiography, help localize occult lesions, and help quantify the amount of depression in displaced fractures and extent of articular surface involvement in comminuted fractures. In the emergency setting, when clinical suspicion of a fracture is high, CT may be performed or this can be done in the outpatient setting, with the patient discharged with crutches and non-weight-bearing instructions.

**Management and Disposition**

All patients with a tibial plateau fracture should be referred for evaluation by an orthopedist, which usually will occur in the ED. In the acute phase, if orthopedic consultation is not obtained in the ED, the fracture should be immobilized in a noncircumferential splint, and the patient should not bear weight on the limb until seen by an orthopedist. Weightbearing generally is delayed until healing is complete, usually 6 to 8 weeks. Stable nondisplaced fractures may be treated with immobilization alone, but instability or significant depression or disruption of the joint surface require surgical management. CT scanning is often required for surgical planning, even when indications for surgery are evident based on the clinical examination and x-ray.

**Fractures of the Intercondylar Eminence (Tibial Spine)**

**Anatomy and Pathophysiology**

The intercondylar eminence, or tibial spine, is the central portion of the proximal tibial surface. The spine has two prominences, the medial tubercle and lateral tubercle. The medial tubercle is larger and more anterior. Two intercondylar fossae are present on the proximal tibial surface, one anterior to the intercondylar eminence and one posterior to it. The ACL and anterior horns of the medial and lateral menisci attach in the anterior intercondylar fossa. The PCL and posterior horns of the menisci attach in the posterior intercondylar fossa. A fracture of the anterior tibial spine usually is associated with an ACL rupture. Tibial spine fractures are more common in children than in adults because the ligaments are stronger than the adjacent physeal plates in the immature skeleton; this fracture may be an isolated injury in the presence of open physes.

Most tibial spine fractures occur as a result of violent knee twisting, hyperflexion, hyperextension, or valgus-varus forces generated during MVCs or athletic activities. The tibial spines are fractured by twisting knee movements, whereas hyperextension or hyperflexion forces may cause avulsion of the intercondylar eminence or cruciate ligaments from their tibial attachments.

**Clinical Features**

After a tibial spine fracture, the patient reports pain and swelling of the knee and may be unable to bear weight on the affected extremity. The examination confirms acute hemarthrosis and may reveal a block to full knee extension. Tense effusion may limit...
ROM, hinder physical examination, and mask ligament disruption. ACL laxity is expected.

Diagnostic Testing

Radiographic evaluation should include standard AP and lateral views; a tunnel view provides a clearer look at the intercondylar area and may reveal the diagnosis. Joint margins should be examined closely for evidence of collateral ligament or capsular bone avulsions. CT sometimes is required to show the location and displacement of the fracture.

Management and Disposition

The knee should be immobilized, and the patient should be given non-weight-bearing instructions and referred to an orthopedist within 3 to 7 days. Most patients are managed conservatively with good results, although some, particularly when reduction cannot be achieved, or there is significant ligamentous disruption, require surgical repair.

Osteochondritis Dissecans

Osteochondritis dissecans is a rare orthopedic disorder of unknown cause (Fig. 50.6). The disorder is found mainly in adolescents and results in partial or total separation of a segment of articular cartilage and subchondral bone from the underlying bone. It is commonly unilateral, involving the non-weight-bearing lateral aspect of the medial femoral condyle, and is thought to be related to acute or chronic trauma. Occasionally, the lateral femoral condyle or inferior patella pole is involved. Patients often have pain, swelling, and giving-way episodes without a history of trauma. Localized tenderness of the condyle often is the only physical finding. Routine radiographic views usually are diagnostic; a subcortical lucency (see Fig. 50.6) can be appreciated, and an osteochondral fragment may be seen separated from the underlying bone. Rarely indicated in the ED, MRI or CT may aid in determining the exact location and extent of the osteochondrotic lesion. ED patients with suspected osteochondritis dissecans should not bear weight until seen by an orthopedist.

Extensor Mechanism Injuries

Anatomy and Pathophysiology

The extensor mechanism consists of the quadriceps muscles, quadriceps tendon, medial and lateral retinacula, patella, patellar tendon, and tibial tubercle (Fig. 50.7). Passive and dynamic stabilization of the patella are aided by the surrounding soft tissue. Although this anatomic complex encompasses the most superficial aspect of the knee, ruptures of the extensor mechanism are infrequent injuries relative to other types of injuries of the knee joint. Disruptions of the extensor mechanism may occur at any level, from the quadriceps muscle to the insertion on the tibial tubercle. Injury generally occurs as a result of sudden vigorous contraction of the quadriceps muscle with the knee in a flexed position, laceration, or direct blow. Rupture of the quadriceps tendon usually occurs at or just proximal to the patellar insertion. Occasionally, the rupture may extend into the vastus intermedius tendon or transversely into the retinaculum. Most patellar tendon ruptures occur at the site of origin on the inferior pole of the patella.

Chronic systemic conditions, including rheumatoid arthritis, gout, systemic lupus erythematosus, hyperparathyroidism, and iatrogenic immunosuppression in organ transplant recipients, may render the tendon vulnerable to rupture. Several studies have implicated the use of steroids or fluorouracil in tendon rupture. In children, quadriceps and patellar tendon ruptures are rare, and muscle tears seem to predominate. In adolescents, patellectomy dysplasia, chronic tendinitis, and use of steroids are predisposing factors. Dysplasia may cause extensor mechanism injury by repetitive tensile overloading; corticosteroids seem to weaken collagen ultrastructure and impair the reparative process.

Clinical Features

Clinical evaluation can elicit the correct diagnosis in most cases of complete disruption of the extensor mechanism. Patients with extensor disruption may have the following signs and symptoms: (1) acute onset of pain, swelling, and ecchymoses over the anterior aspect of the knee and a palpable defect in the patella, quadriceps tendon, or patella tendon; (2) loss or limitation of ability for active
leg extension—extension lag usually is seen when extension for the last 10 degrees is performed haltingly or with difficulty; (3) high-riding patella (patella alta), with patellar tendon rupture and superior retraction; and (4) low-riding patella (patella baja), with quadriceps tendon rupture and inferior retraction. Partial disruptions may be difficult to diagnose on clinical examination and may require MRI for confirmation.

Diagnostic Testing
Standard AP and lateral radiographs should be obtained and may reveal characteristic findings, possibly including obliteration of the quadriceps or patella tendon, poorly defined suprapatellar or infrapatellar soft tissue mass, soft tissue calcific densities, or displaced patella (Fig. 50.8). Patella alta may be sought on the lateral radiograph with use of a ratio of patellar length to patellar tendon length (Insall-Salvati ratio). If this ratio is less than 0.8, patella alta is present. The degree of flexion should not affect this ratio, which relies on the inelasticity of the patellar tendon. Obliteration of the extensor tendons may be caused by a frayed tendon and surrounding hematoma. A soft tissue mass represents proximal or distal retraction of the torn tendon. Calcific densities may represent avulsed bone fragments of the patella or tibial tubercle or dystrophic calcifications in the substance of the tendons. Despite these multiple radiographic signs, the correct diagnosis is infrequently made by plain radiography in cases of incomplete quadriceps tendon rupture. MRI shows the entire extensor mechanism and is the best imaging modality. MRI usually is reserved for patients with possible incomplete disruption or with a complication of intraarticular derangements.

Management
Treatment of acute extensor mechanism injuries produces a much better clinical outcome if instituted early, within 2 to 6 weeks of the initial injury. All patients with partial or complete tears of the extensor mechanism should be referred for orthopedic care.

If the tear is only partial, immobilization with the knee in full extension for 4 to 6 weeks is the treatment of choice. Surgical intervention is required for reattachment of complete tendon ruptures, and repair should be performed as soon as possible after injury for the best results to be achieved.

Patellar Fractures

Anatomy and Pathophysiology
The patella is the largest sesamoid bone in the body. It is held in place by the quadriceps tendon, patellar ligament, and medial and lateral retinacula. As an integral part of the extensor mechanism, the patella increases the effective lever arm of the quadriceps by providing anterior displacement of the quadriceps tendon. All fractures of the patella, except for small avulsion fractures of the rim, are considered intraarticular.

Patellar fractures are classified as transverse, stellate, or comminuted, longitudinal or marginal, proximal pole or distal pole and, rarely, osteochondral. They may be displaced or nondisplaced and occur from direct or indirect forces or from dislocation. The most common fracture pattern is the transverse fracture (accounting for 50%–80% of cases). This type often is seen in young adults and usually results from a powerful contractile force transmitted from the quadriceps tendon. This force may pull the superior portion of the patella upward, leading to wide displacement. In such cases the medial and lateral retinacula are usually disrupted, resulting in significant functional disability; active extension is impossible. Nondisplaced transverse patellar fractures usually are caused by a direct blow to the anterior aspect of the patella (eg, a fall on the knee or a direct blow sustained in vehicular trauma). The retinaculum and extensor mechanism usually remain intact, and the patient retains limited functional ability for active extension. Stellate and comminuted fractures account for 30% to 35% of all patellar fractures and commonly result from a direct impact. The fracture elements often appear as separated fragments on plain radiographs but are held in place and supported by the medial and lateral retinacula and the overlying soft tissues. Small

![Fig. 50.8. Rupture of the patellar tendon, resulting in the high-riding patella in frontal (A) and lateral (B) projections. B, The normally lucent infrapatellar portion of the joint space is dense (asterisk), representing blood within the anterior compartment. (From Harris JH Jr, Harris WH: The radiology of emergency medicine, ed 3, Baltimore, 1993, Williams & Wilkins.)](image-url)
proximal fragments are at risk for avascular necrosis because the patellar blood supply is central and inferior. Longitudinal or marginal vertical patellar fractures are less common, are usually the result of direct injury, and involve the lateral facet.

Clinical Features

On physical examination, tenderness, swelling, and ecchymosis over the patella and prepatellar bursa are noted. Active extension may be limited or absent, depending on the fracture pattern and amount of fragment displacement. Associated injuries may include fractures of the femoral neck, dislocation of the hip, and acetabulum fractures.

Diagnostic Testing

Radiologic evaluation of patellar fractures should include standard AP, lateral, and sunrise views. Most patellar fractures are obvious on plain radiographs, but vertical marginal fractures may be difficult to identify; they are obscured by the femur on the AP view and not seen at all on the lateral view. Close examination of sunrise (or equivalent) views may reveal an osteochondral avulsion fragment or marginal fracture (Fig. 50.9). Bipartite and multipartite patellae are common normal variants and should not be confused with fractures. Ossification centers are found at the upper outer quadrant of the patella and have smooth cortical margins, but differentiating physeal lines from fractures can be difficult. Comparison radiographs may be helpful because these anatomic anomalies often are bilateral. In some cases, MRI or arthroscopy may be needed to identify occult marginal fractures or free osteochondral fragments.

Management

For initial management, a knee immobilizer may be used. Patients should be instructed to use crutches, with partial weightbearing as tolerated, and should be referred for orthopedic evaluation within 1 week.

For widely displaced transverse fractures, open reduction and internal fixation are necessary for optimal results. Although operative techniques vary among surgeons, tension band wire and suturing of the retinaculum often are used. A knee immobilizer or long leg posterior splint can be used initially to immobilize the extremity before definitive care is provided. Treatment options for displaced comminuted fractures include open reduction, internal fixation, and partial or complete patellectomy.

Persistent patellofemoral pain and osteoarthritic symptoms are reported as late sequelae of patellar fractures in approximately 50% of patients.

Patellar Dislocation

Anatomy and Pathophysiology

Traumatic patellar dislocation is a relatively common knee injury, with a high frequency of recurrence. It is more common in children than in adults. Most cases are lateral, and the mechanism of injury usually is a direct blow to the anterior or medial surface of the patella. It may occur from an athletic injury caused by a valgus stress combined with flexion and external rotation. In nearly all cases, disruption or sprain in the medial patellar retinaculum results from stretching of this structure as the patella subluxes laterally; subluxation usually indicates a stretched medial retinaculum, and dislocation suggests a tear.

Clinical Features

Patients with lateral patellar dislocation may complain of the knee giving out, accompanied by pain and swelling. Inability to bear weight and inability to flex the knee are common complaints. There may be a history of previous dislocation. Examination reveals a defect anteriorly, with the patella deviated laterally. Tenderness along the medial joint line usually can be elicited by palpation, and an effusion may be present. Acute hemarthrosis is usually seen if there is an associated osteochondral fracture. Osteochondral fractures typically occur on the articular surface of the patella and may involve only cartilage (chondral fractures) or may include a piece of underlying cortical bone. Patellar dislocations may reduce spontaneously, or the patient may self-reduce the dislocation, usually followed by formation of a large effusion.

The patellar apprehension test is used to aid the clinical identification of patients at risk for patellar dislocation or subluxation. The apprehension sign refers to the combination of manifestations of anxiety and anticipatory reactions observed in the patient when the examiner attempts to slide the nondisplaced patella laterally. A positive result on the apprehension test indicates a tendency for patellar subluxation or dislocation. This test has no proven value and is not necessary in a patient with acute patellar dislocation, but it may be useful in establishing the diagnosis in patients who report an event that resolved spontaneously.

Diagnostic Strategies

Standard AP and lateral radiographic views generally are adequate for diagnosis. Obtaining a sunrise (skyline) view usually is not possible because of pain and inability to flex the knee. Radiographic findings include lateral deviation of the patella out of the trochlear groove, usually with an effusion. Radiographs should be examined for evidence of avulsion fractures.

Management and Disposition

After dislocation is diagnosed, closed reduction should be attempted. Usually, the procedure is very straightforward, involving simple, slow, gentle, passive extension of the knee, with inferomedial pressure on the patella. If done with appropriate care,
patient discomfort often is minimal, and the patient does not require procedural sedation. If the procedure is painful, or the patient is excessively anxious, appropriate sedation and analgesia are used. Application of downward pressure to the lateral aspect of the patella can help in reduction by unlocking the medial patellar facet. Postreduction radiographs are recommended and should reveal the patella in the trochlear groove. Osteochondral avulsion fragments may be visualized radiographically, and postreduction radiographs should be examined carefully for their presence. Radiographically evident intraarticular loose bodies may require arthroscopic removal.

Typically, traumatic patellar dislocations occur with disruption of the medial retinaculum but an intact lateral retinaculum, preventing internal rotation. Dislocations irreducible by conventional methods may be associated with significant internal rotation and lateral retinaculum pathology.

After successful reduction, the knee should be immobilized in full extension, and the patient may be discharged with referral for orthopedic or primary care follow-up within 2 weeks. Ice, elevation, non-weight-bearing status, and analgesia are helpful. Although the incidence of recurrence may be decreased with appropriate therapy and proper patient selection, up to 44% will experience a recurrent dislocation, and more than 50% of all patients with a primary patellar dislocation will continue to have symptoms of instability or anterior knee pain and may require surgery.

Cruciate and Collateral Ligament Injuries

Ligament injuries to the knee may involve any or all of the ligaments and may range in severity from a mild sprain to complete tears. Collateral ligament injury usually causes tenderness and pain along the joint line. Cruciate injuries pose more of a diagnostic dilemma because they are intraarticular.

Clinical Features

Cruciate Ligament Injuries. The cruciate ligaments are so named (Latin crux, meaning “cross”) because they cross each other between their attachments. They are the primary stabilizers for anterior and posterior displacement of the tibia on the femur. The ACL extends obliquely upward, medially, and posteriorly from the anterior intercondylar area of the tibia to the medial aspect of the lateral femoral condyle. The ACL prevents excessive anterior displacement of the tibia on the femur and helps control rotation and anterior intercondylar area of the tibia to the lateral aspect of the knee. It is the most common injured major ligament of the knee, with more than 100,000 new ACL tears occurring in the United States annually. The PCL passes upward, laterally, and posteriorly from the posterior intercondylar area of the tibia to the lateral aspect of the femur condyle of the femur. The PCL prevents excessive posterior displacement of the tibia on the femur and helps control rotation and lateral rotary instability. The MCL is a two-part structure with a long superficial and deep capsular component; the latter attaches to the medial meniscus and acts as a stabilizer for this structure. The MCL usually is injured by a direct blow or impact to the lateral aspect of the knee, which imposes a valgus stress. MCL injury is the most common isolated knee ligament injury and is the injury most commonly associated with ACL injury. MCL injury usually does not require surgical treatment.

Collateral Ligament Injuries. The medial stabilizers of the knee are the LCL and lateral joint capsule. Secondary contributors to lateral stability are supplied by the iliotibial (IT) band, biceps tendon, and popliteal arcuate complex in the posterolateral corner of the knee. Resistance to varus stress is provided mainly by the LCL. Fibers descend from the lateral femoral condyle and insert at the fibular head. The lateral ligaments are under tension during standing and walking, when they are at or near maximal extension. The LCL usually is injured by a mechanism of hyperextension with varus stress, commonly accompanied by a direct blow or rotation. Injuries to the LCL are less common but more disabling than injuries of the MCL. The lower incidence of injury is attributed to the greater mobility of the LCL and overall greater stability of the lateral compartment. Varus injury is uncommon because the inner aspect of the knee is protected by the opposite leg. The forces necessary to produce LCL injury usually are greater than the forces required for medial injury, which partially explains the high frequency of associated injuries accompanying LCL injury. The tendon of the biceps femoris muscle attaches to the head of the fibula; the peroneal nerve passes just inferior to this. Because of this relationship, common peroneal nerve injury and biceps femoris tendon injury are possible although uncommon in patients with LCL injury.

The accuracy of the knee examination for ligamentous damage is enhanced if done soon after injury and before the onset of swelling and pain, but the patient may not tolerate the examination anyway, and muscle spasm can obscure findings. In any case, ligamentous injuries are not emergencies and can be diagnosed definitively after the acute phase has passed. Focal tenderness at
the origin or insertion sites suggests collateral ligament trauma but also can occur with muscular injury, osseous pathology, or meniscal tear.

Diagnostic Testing
The goal of radiographic investigation is to identify associated fractures. The initial radiographic evaluation should include AP, lateral, intercondylar notch, and sunrise views. Each radiograph should be evaluated for possible osteochondral injuries, loose bodies, or avulsion injuries at the attachment sites of ligaments. The lateral capsular sign, associated with the Segond fracture (see Fig. 50.5) and fracture of the posterior aspect of the lateral tibial plateau, commonly is associated with a ACL tear.

Arthroscopy is the gold standard for the diagnosis of soft tissue injuries of the knee (ligaments or menisci). MRI is useful but may miss small tears and anatomic abnormalities and, even if findings are normal, arthroscopy may still be necessary if symptoms persist. Moreover, abnormalities discovered at arthroscopy can be repaired. Therefore, many orthopedic surgeons recommend arthroscopy rather than MRI for diagnostic evaluation of knee pain when the causative disorder is not apparent on physical examination.

Management and Disposition
ED management consists compressive dressing from the foot to thigh, ice, simple analgesia with acetaminophen or a nonsteroidal antiinflammatory drug (NSAID) and no or minimal weight bearing. Orthopedic evaluation should take place within 1 week, when feasible. In the orthopedic surgeon's office, isolated collateral ligament injuries usually are managed nonoperatively, provided that the ACL is intact. Patients may be placed on a regimen of partial weightbearing or non–weight-bearing status with the use of crutches. A rehabilitative exercise program for quadriceps and hamstring strengthening may be instituted when the acute injury has resolved.

There is controversy among orthopedists regarding management of ACL tears because short-term disability and long-term arthritic sequelae are difficult to predict. Most young patients with a complete ACL tear who are active in sports will have reconstructive surgery to stabilize the knee. Surgical repair usually is performed arthroscopically after a delay of 2 to 3 weeks to allow swelling to subside. Older patients and patients who do not participate in active sports may be managed conservatively with muscle strength training.

Isolated PCL injuries are unusual and are generally managed nonoperatively. These injuries often are painful but usually do not lead to instability. Rehabilitation involves quadriceps strengthening and functional bracing. Over 10 to 20 years, degenerative changes of the articular surface may result in stiffness and pain.

Meniscal Injuries
Anatomy and Pathophysiology
The medial and lateral menisci are crescent-shaped fibrocartilaginous cushions that sit on the superior articular surface of the tibia and provide a gliding surface for the femoral condyles. They function as shock absorbers and aid in the distribution of stress across the joint surface by providing a larger area of contact. They also act as secondary stabilizers by deepening the tibial plateau. Normal tibiofemoral articulation and function depend on meniscal integrity; damage or loss leads to osteoarthritis. The medial meniscus is firmly attached anteriorly and posteriorly to the joint capsule. The lateral meniscus is less firmly attached to the capsule and more mobile. The menisci move slightly forward with extension and backward with flexion. Because of its greater mobility, the lateral meniscus is less vulnerable to injury. The meniscus is avascular except at the peripheral third, which has the greatest potential to heal after injury.

Meniscal injury classically manifests with pain and tenderness at the joint line, effusion, and clicking or locking of the knee. Because the menisci are much less vascular than the cruciate ligaments, significant hemarthrosis is usually not seen with isolated meniscal injury. Locking results from a meniscal fragment blocking joint movement. Injury to the menisci may be from a single traumatic episode, degenerative process, or combination. The mechanism usually involves a twisting maneuver on a weight-bearing knee. The force required sometimes can be as slight as arising from a chair while turning. Most meniscal tears are posterior.

Clinical Features
An isolated meniscal tear should be suspected in a patient with a history of intermittent locking, effusion, giving way, and pain and physical examination findings of joint line tenderness.

The cardinal sign of a meniscal tear is local pain and tenderness along the joint line. Joint line pain and tenderness are especially apparent with extremes of flexion and extension. Not all tears of the menisci are symptomatic. Degenerative lesions of the posterior horn are relatively common in middle age and later and may be asymptomatic. The differential diagnosis for a torn meniscus is extensive and includes loose bodies, osteochondrotic lesions, tibial spine fractures, patellofemoral pain syndrome, popliteal tendinitis, plica syndromes, inflammatory arthritis, and discoid menisci, with or without tears. Meniscal tears commonly accompany ACL tears.

Diagnostic Testing
Diagnosis of acute meniscal injury is difficult, more so in the presence of another acute knee injury, especially an ACL tear. Meniscal injury cannot be diagnosed by plain radiography or CT scanning. Arthroscopy is the gold standard for diagnosis; MRI is an alternative but may miss some meniscal tears.

Management and Disposition
Definitive treatment of a meniscal injury is not urgent. Unless the knee is locked and cannot be extended or flexed, a patient with a meniscal tear should be managed with analgesics, immobilization, ice, non–weight-bearing status, and referral for orthopedic or primary care follow-up. The locked knee requires acute orthopedic consultation if a knee immobilizer cannot be applied. Surgery is reserved for patients with persistent symptoms that limit activity, because research has suggested that surgical repair is no better than conservative management.

Overuse Syndromes
Overuse syndromes result from repetitive trauma and inflammation. The typical complaint is knee pain, often localized to one of three particular areas—the medial aspect, lateral aspect, or perilpatellar region. Medial knee pain may be caused by a subluxation of the patella, stress fracture of the upper third of the tibia, anserine bursitis or tendinitis, and MCL strain related to excessive foot pronation. Lateral knee pain may be caused by IT or popliteal tendinitis, LCL strain, or stress fracture of the fibula. Anterior pain is typical of lateral patellar compression syndrome, peripatellar tendinitis, and patellofemoral syndrome, the most common cause of knee pain.
**Patellofemoral Pain Syndrome**

**Anatomy and Pathophysiology**

The patellofemoral pain syndrome refers to the clinical presentation of anterior knee pain related to changes in the patellofemoral articulation. Chondromalacia patellae describes softening of the articular cartilage. Correlating pathologic changes on the surface of the patella and clinical symptoms has been difficult, and the pain mechanism has not been precisely defined.

**Clinical Features**

Patellofemoral pain syndrome is the most common cause of knee pain. Affected patients generally are 10 to 20 years of age and often have difficulty describing their symptoms clearly. The pain usually begins gradually and commonly is not related to trauma. One knee is more affected than the other. The knee is more painful with prolonged flexion (eg, from sitting in a movie theater), and the discomfort typically is accentuated by stair climbing and kneeling. The patient may have instability related to patellar subluxation or dislocation. The syndrome occurs in athletes and in older patients who have arthritis affecting the patellofemoral joint. Considerations in the differential diagnosis include tears of the menisci, plica syndrome, inflammatory or degenerative arthritis, ligament injuries, and overuse syndromes (eg, prepatellar bursitis, patella tendinitis).

The physical examination should begin with observation. The patient may ambulate with an antalgic gait. A tibiofemoral joint effusion may be present. The patellar facets may be tender. Classically, compression of the patella against the femur with the knee extended causes pain. There may also be apprehension regarding medial or lateral subluxation.

**Diagnostic Testing**

Patellofemoral pain syndrome is a clinical diagnosis; radiography is usually not required and, when performed, images are usually normal. More advanced studies are not indicated unless alternative diagnoses are being considered.

**Management**

Most patients, regardless of the cause of their condition, respond to a rehabilitation program. Conservative treatment for patellofemoral pain usually is effective, with most patients responding to one or more of four types of treatment: (1) exercises to strengthen the quadriceps; (2) brace support of the patellofemoral mechanism; (3) activity modification limiting flexion; and (4) medications such as NSAIDs for pain. The initial goal is to reduce pain and improve function, with emphasis placed on strengthening the vastus medialis oblique muscle. The patient should receive appropriate referral to ensure that an optimal rehabilitative scheme is designed.

**Iliotibial Band Syndrome**

**Clinical Features**

The IT band is a strip of fascia lata that extends from the iliac crest to the lateral tibial tubercle. It connects the lateral femoral condyle and lateral tibia and stabilizes the knee joint in extension. Irritation from overuse can cause inflammation of a bursa underlying the IT band at the lateral femoral epicondyle, resulting in lateral knee pain. The syndrome is most common in distance runners and is more likely in hyperpronators. Physical findings include localized tenderness of the lateral femoral epicondyle and IT tightness or pain, elicited by Ober’s test or a related test. In Ober’s test, the patient lies on his or her side with the unaffected leg down, flexed to 90 degrees at the hip and knee. The affected hip is abducted, the knee is extended, and then the hip is allowed to return to neutral adduction with gravity. Failure of the hip to adduct fully with gravity or reproduction of pain at the lateral knee indicates IT tightness or inflammation, respectively. Radiographs are not indicated. Considerations in the differential diagnosis include early degenerative joint disease, cystic or torn lateral meniscus, lateral capsular strain, lateral tibial or femoral condyle osteonecrosis, stress reactions, chondromalacia, and popliteus tendinitis.

**Management and Disposition**

Treatment involves rest, ice, and NSAIDs during the acute phase, followed by an IT band stretching regimen, improved footwear and orthotics when indicated, and gradual return to previous levels of activity. Steroid injections are helpful for refractory cases, and surgical release is uncommonly required.

**Peripatellar Tendinitis**

Peripatellar tendinitis, or jumper’s knee, refers to a spectrum of patellar tendon and extensor mechanism abnormalities that result from chronic repetitive stress from jumping, running, or cutting. Microscopic tears occur in the tendon. Treatment includes NSAIDs, rest, and activity modification. Local steroid injections are not recommended. For highly competitive athletes and patients for whom conservative treatment is ineffective, surgery with debridement of abnormal tissue may be performed.

**Plica Syndrome**

Plicae, or redundant folds of synovium, are normal embryologic structures that persist in the adult knee. Repetitive bouts of synovitis within the plica may result in a tight inelastic band that interferes with knee motion. Patients typically complain of pain over the region of the medial femoral condyle brought on by activity but also occurring after sitting for prolonged periods. A snapping sensation is another commonly reported symptom as the plica sweeps across the femoral condyle. Other nonspecific symptoms include intermittent swelling, locking, weakness, and stiffness. The physical examination often elicits tenderness over the medial femoral condyle but not the medial joint line; the latter finding would be more typical of a medial meniscal lesion. An effusion, crepitus, loss of motion, quadriceps atrophy, and positive result on McMurray’s test may be noted as well.

Plain radiography may be necessary to exclude other causes of knee pain but is of no value in diagnosing plica syndrome, for which arthroscopy usually is required. Most plicae are incidental arthroscopic findings unrelated to underlying knee pathology. Medial patella pain is more likely to be related to patellofemoral maltracking than to plica syndrome. Likewise, anteromedial joint line tenderness is more likely to be related to a meniscal tear than to a pathologic plica.

Treatment involves rest and NSAIDs. When the acute symptoms have resolved, a rehabilitation program is instituted to emphasize quadriceps strengthening and stretching. Arthroscopic excision of pathologic plica may be necessary if conservative treatment fails.

**Popliteus Tendinitis**

The popliteus is a small flat muscle that originates on the lateral femoral condyle and inserts on the posteromedial tibia, capsule, and lateral meniscus. It passes beneath the lateral head of the
Bursitis

The knee has several bursae, which decrease friction between moving structures. They usually are thin but, with repeated stress, may become thickened and fluid-filled. The prepatellar bursa is located between the patella and skin. The superficial infrapatellar bursa is located between the tibial tubercle and skin. The deep infrapatellar bursa is located between the posterior margin of the distal part of the patellar tendon and anterior aspect of the tibia. The suprapatellar bursa is not a true bursa but rather is an extension of the tibiofemoral joint capsule. The anserine bursa separates the pes anserinus from the distal portion of the MCL and medial tibial condyle. As noted previously, pes anserinus means “goose foot” and anserine means “related to the pes anserinus.” The term pes anserinus derives from the fact that the bursa underlies the anserine tendon, a three-forked structure constituting the insertion of the gracilis, sartorius, and semitendinosus muscles.

Bursitis is caused by repeated stress, infection, local trauma, crystal deposition, or systemic inflammatory arthropathy. It is important to differentiate bursitis from a joint effusion. Prepatellar bursitis is characterized by swelling, with effusion of the superficial bursa overlying the lower pole of the patella. Usually, passive motion is fully preserved, and the pain is mild. The disorder usually is caused by pressure from repetitive kneeling on a firm surface (so-called housemaid’s knee). The prepatellar bursa also is a common site of septic bursitis, and a common error is to confuse this entity with a septic knee (involving the tibiofemoral joint).

Anserine bursitis involves pain and tenderness at the proximal medial tibia, a few centimeters inferior to the medial joint line. It usually occurs in obese women in association with osteoarthritis of the knee but also may occur from overuse, especially in runners. It is characterized by a relatively abrupt onset of knee pain, with localized tenderness and puffiness at the pes anserinus. It can be confused with a medial meniscal or MCL tear.

Radiographic studies are not required but, when obtained, may reveal soft tissue swelling. Ultrasound imaging also may detect the fluid collection. MRI may be helpful but is not required on an urgent basis. With any uncertainty regarding the possibility of infection, the bursa fluid should be aspirated, and Gram staining, culture, cell count, and crystal analysis of the aspirate should be performed.

Septic (bacterial) bursitis requires antibiotic treatment, with operative drainage in refractory cases. Aseptic (inflammatory) bursitis is treated with ice, rest, antiinflammatories, injection of bupivacaine and, when infection is not suspected, corticosteroids. All the bursae of the knee may be injected with steroids; in the ED, steroid injection of the anserine and prepatellar bursae is most common.

Baker’s Cyst

Baker’s cyst (popliteal cyst) is a herniation of the synovial membrane through the posterior aspect of the capsule of the knee (Fig. 50.10). It results from an enlarging knee effusion of any cause. A mass is palpable in the posteromedial corner of the knee and often produces pressure, pain, and limitation of ROM. Rupture of the bursa, with resultant escape of fluid into the calf, may produce a clinical picture similar to that of deep vein thrombosis or compartment syndrome. In this circumstance, ruptured

Fig. 50.10. Baker’s cyst is an extension of the semimembranosus bursa posteriorly. This bursa often is connected with a joint cavity.
Baker’s cyst is a diagnosis of exclusion (ie, thrombosis should be ruled out). Treatment is directed at the underlying intraarticular pathology.

LEG

PRINCIPLES

Anatomically, the leg is comprised of the tibia, fibula, and associated soft tissues, whereas the thigh is comprised of the femur and its soft tissues. Bearing the full weight of the body, the leg is subject to enormous stress, and the tibia is the most commonly fractured long bone. Moreover, the tibia is poorly covered by soft tissue anteriorly, making infection and delayed healing common.

ANATOMY AND PATHOPHYSIOLOGY

The bony structure of the lower leg is relatively simple, consisting of the tibia and fibula. The fibula does not bear weight. The shaft of the tibia is triangular in cross section and poorly covered with soft tissue over its anteromedial aspect. It is the most common long bone to be fractured and sustain open fracture. The lack of overlying soft tissue results in a tenuous blood supply, which increases the rate of osteomyelitis and contributes to delayed union and nonunion, which are common in tibial fracture.

The distal end of the tibia is expanded and bears an additional surface feature, the fibular notch, for the lower tibiofibular joint. The medial malleolus projects from the distal medial aspect of the tibia and has a posterior groove for the tibialis posterior tendon. The inferior surface of the distal tibia is covered with articular cartilage and forms the tibial plafond, the upper anterior surface of the ankle joint. The fibula, in contrast to the tibia, is covered by soft tissue except at the ankle, where it is subcutaneous and easily palpable. The fibula is composed of the head with its styloid process, neck, shaft, and lateral malleolus of the ankle.

The tibia and fibula are connected by superior and inferior tibiofibular joints and a strong interosseous membrane or syndesmotic ligament. The latter is a fibrous band that has particular importance at the distal portion of the lower leg, where it is responsible for keeping the tibia and fibula closely approximated to provide a stable ankle mortise.

The vascular supply of the lower leg is derived from the popliteal artery, which trifurcates to form three branches—the anterior tibial artery, posterior tibial artery, and peroneal artery. The anterior tibial artery can be assessed by palpating the dorsalis tibial artery, posterior tibial artery, and peroneal artery. The tibial nerve, which supplies sensation to the plantar aspect of the foot.

clínica

CLINICAL FEATURES

Proximal Extraarticular Tibial Fractures

Subcondylar Tibial Fractures

Subcondylar tibial fractures usually are associated with tibial plateau fractures, especially bicondylar fractures. Subcondylar fractures involve the proximal tibial metaphysis and typically are transverse or oblique. The mechanism of injury involves a rotational or angular stress accompanied by vertical compression. Examination reveals tenderness and swelling of the involved area. A hematohrosis may indicate extension of the fracture into the joint or associated ligamentous injury. Routine radiographic views usually are adequate in showing the fracture line. ED management includes ice and immobilization with a long leg posterior splint. Stable extraarticular nondisplaced transverse fractures usually are treated conservatively with a long leg splint, followed by delayed casting on an outpatient basis because of the risk of swelling and compartment syndrome. In children, casting (with adequate padding) is sometimes performed acutely. Comminuted fractures or fractures associated with an intraarticular component require open reduction and internal fixation, which may be undertaken acutely.

Tibial Tubercle Fractures

Anatomy and Pathophysiology. The tibial tubercle is located at the proximal anterior border of the tibial shaft and is the insertion point of the patellar ligament. The proximal tibial epiphysis and tibial tuberosity develop from two separate ossification centers that coalesce during adolescence. Epiphyseal ossification terminates in late adolescence.

Avulsion fractures of the tibial tubercle are uncommon. They occur predominantly in adolescent boys. The injury typically occurs near the end of growth, when enchondral ossification of the physeal cartilage of the tibial tubercle occurs. Avulsion fractures mainly occur as an indirect injury during activity. The mechanism of injury has been described as a violent flexion of the knee against a tightly contracted quadriceps muscle, which also can cause patellar tendon rupture. The Watson-Jones classification describes three grades of injury depending on the extent of displacement (Fig. 50.11):

- Type I injuries, the tubercle is hinged upward, without displacement from the proximal base.
- Type II injury has a small portion of the tubercle avulsed but it is retracted proximally; the articular surface is not involved.
- Type III fractures are more severe and extend across the articular surface; displacement of the fragment and often comminution are features.

Clinical Features. Physical examination reveals acute tenderness and swelling at the anterior aspect of the knee and proximal tibia. Depending on the type of injury, functional disability may range in severity from extensor lag to complete loss of active extension. Hemarthrosis is evident with type III injury because of intraarticular fracture extension across the proximal epiphysis.

Diagnostic Testing. Plain radiographs usually are adequate for diagnosis. The lateral view shows the avulsion fracture, number of fragments, and amount of displacement. Swelling of the overlying soft tissue is evident. Comparison views may be necessary when a type I injury is suspected.

Management. Treatment depends on the degree of displacement and presence of joint involvement. Nondisplaced type
I avulsions are treated with cast immobilization, with the knee in extension, until healing results. Minimally displaced type II avulsions may be treated similarly if the displacement can be reduced by external manual maneuvers. Displaced type III fractures are treated by open reduction and internal fixation to restore proper biomechanics and joint congruity. Fixation screw and tension band wiring techniques have yielded excellent results. After a period of immobilization and progressive rehabilitation, most patients are able to return to full activity.

Complications of tibial tubercle fractures are rare and include genu recurvatum (backward curvature of the knee), patella alta, meniscal tears, failure of surgical fixation, and subsequent heterotopic ossification and osteonecrosis of the tubercle. If the involved growth plates are closing at the time of injury, premature physeal closure can result in a significant recurvatum deformity, but this rarely occurs.

Tibial Shaft Fractures

Anatomy and Pathophysiology

The tibia and fibula are tightly bound to each other by the syndesmotic ligament. This strong band of tissue can transmit energy so that the tibia and fibula may be fractured at nonadjacent sites. The fibula remains intact in only 15% to 25% of tibial shaft fractures. Tibial shaft fractures are associated with a high incidence of infection, delayed union, nonunion, and malunion, in part because of the poor soft tissue coverage of the anterior tibia.

Transverse tibial diaphyseal fractures typically result from high-energy direct trauma. Low-energy rotatory and compressive forces often result in spiral or oblique fractures.

Tibial fractures also may occur without trauma. Stress fractures usually occur in the tibial shaft. Pathologic fractures may be caused by metabolic bone disease, osteomalacia, or neoplasm.

Clinical Features

Tibial shaft fractures cause pain, swelling, and localized deformity, usually angulation or rotation of the foot. Determination of vascular integrity is the priority. Distal dorsalis pedis and posterior tibial pulses should be assessed; however, vascular injury is a rare complication of these fractures. Neurologic injury, by contrast, is common, particularly injury of the peroneal nerve. Motor function of the peroneal nerve is checked by testing active ankle and toe dorsiflexion (deep peroneal nerve) and active foot eversion (superficial peroneal nerve). Sensory function of the peroneal nerve is documented by testing sensation in the first dorsal web space in the foot (deep peroneal nerve distribution) and sensation of the dorsal lateral foot (superficial peroneal nerve distribution). Integrity of the posterior tibial nerve is assessed by checking for the presence or absence of plantar sensation. Significant soft tissue damage also may accompany tibial shaft fractures. Compartment syndrome may be a complication of tibial fractures that usually develops within the first 24 to 48 hours.

Diagnostic Testing

AP and lateral radiographic studies document the fracture, define the fracture pattern, and identify any associated bone loss (Fig. 50.12). The knee and ankle should be included in both views, and
Maisonneuve fracture, view. The fibula in all medial ankle injuries. Ankle mortise, for which surgical fixation is required. The possibility of this injury indicates the need for examination of the proximal fibula in all medial ankle injuries.

**Management and Disposition**

The initial management of closed tibial shaft fractures consists of immobilization in a long leg posterior splint applied with the knee in 10 to 20 degrees of flexion. The splinting procedure may require analgesia and sedation. In general, after fractures have been immobilized, pain decreases. If the patient reports continued severe pain after immobilization, a complication such as compartment syndrome, nerve root compression, or limb ischemia should be considered. Circumferential casts generally are avoided in the acute setting because of the risk of compartment syndrome, although some orthopedists will cast pediatric fractures in the acute phase. Initial hospitalization is indicated for most patients with significant tibial shaft fractures to allow adequate pain control and observation for compartment syndrome.

Open fractures should be covered by a sterile dressing. Antistaphylococcal antibiotics (typically, cefazolin, 1 to 2.5 mg/kg/dose every 8 to 12 hours) should be given. Gentamicin (2 mg/kg tid) may be added for severely contaminated wounds. Tetanus vaccination status should be updated as indicated. A long leg posterior splint should be applied. This applies to all open fractures.

Emergency operative débridement with external or internal fixation is recommended as soon as possible for open tibial fractures with significant soft tissue disruption. Osteomyelitis is more likely with open fracture, significant soft tissue disruption, and longer time from contamination to definitive surgical management.

In general, tibial fractures are slow to heal. The average time to union is approximately 20 weeks for stable tibial shaft fractures caused by a low-energy mechanism and more than 30 weeks for unstable fractures caused by a high-energy mechanism. Delayed union describes fracture segments that have not united after 24 weeks or that show no radiographic evidence of callus formation for 3 consecutive months. Nonunion is a radiographic diagnosis, with a finding of rounded, well-corticated edges of the major fracture fragments. It is much more common in adult long bone fractures than in childhood fractures, which generally heal rapidly. Delayed vascular injuries, including pseudoaneurysm, arteriovenous fistula, and deep vein thrombosis, also may occur as a complication of tibial shaft fractures. Fat embolism also may occur acutely, especially after reamed nailing. Additional late complications include malrotation of the leg, refracture, and reflex sympathetic dystrophy.

**Proximal Fibula Fractures**

**Anatomy and Pathophysiology**

Isolated fibular fractures are relatively unimportant because the fibula is a non-weight-bearing bone. The mechanism of injury usually is a direct blow to the lateral aspect of the leg or an indirect varus stress to the knee. An important exception is the Maisonneuve fracture (Fig. 50.13). This injury involves a medial ankle disruption (deltoid ligament tear or medial malleolar fracture), with complete tearing of the syndesmotic ligament joining the tibia and fibula and fracture of the proximal fibula. Consequently, the fibula floats free relative to the tibia, resulting in an unstable ankle mortise, for which surgical fixation is required. The possibility of this injury indicates the need for examination of the proximal fibula in all medial ankle injuries.

**Clinical Features**

Isolated fibular shaft fractures cause lateral leg pain that is exacerbated by walking. Local pain, swelling, and tenderness at the fracture site may be elicited, although signs and symptoms can be subtle. A thorough evaluation should be done to exclude serious associated occult neurovascular or ligamentous injuries. The common peroneal nerve courses around the neck of the fibula and may be contused or lacerated at the time of injury. The LCL of the knee may be ruptured or strained in association with the fracture, and anterior tibial artery injury with thrombosis may occur.

**Diagnostic Testing**

AP and lateral radiographic views should include the knee and ankle joints.

**Management and Disposition**

Isolated fibular shaft fractures are treated symptomatically with ice, analgesia, and non–weight-bearing status. Immobilization in a long leg cast is rarely done but may provide symptomatic relief beginning 2 days after the acute injury. Weightbearing may be advanced progressively as tolerated; pain should be avoided. Patients with nondisplaced or minimally displaced fractures may have little pain and tolerate crutch walking without casting. In general, isolated fibula shaft fractures can be managed on an outpatient basis and heal without complication.

For severely displaced fibular shaft fractures or fractures with associated peroneal nerve deficit (ie, footdrop), orthopedic consultation is indicated. Cast immobilization is not recommended in cases with concomitant nerve damage, and follow-up is scheduled at a shorter interval from injury. Elective surgical repair may
be indicated if function does not return. A Maisonneuve fracture results in an unstable ankle, and open reduction and internal fixation usually are required.

**Proximal Tibiofibular Joint Dislocations**

**Anatomy and Pathophysiology**

The proximal tibiofibular joint is a small synovial joint between a circular or oval facet on the head of the fibula and a similar facet on the inferior aspect of the lateral tibial condyle. The proximal tibiofibular joint is stabilized by the joint capsule and anterior and posterior tibiofibular ligaments. Dislocation of the proximal tibiofibular joint is rare, occurring most commonly in adolescents and young adults because of its association with MVCs and sports injuries. Several types of dislocations of the joint have been described; anterolateral dislocation is the most common and usually is caused by a fall on a flexed abducted leg. Posterior medial dislocation generally is caused by a direct blow to the flexed knee and is more often associated with peroneal nerve injury. Superior dislocation is associated with ankle diastasis and typically occurs simultaneously with an ankle fracture.

**Clinical Features**

The patient may complain that the knee feels out of joint or, if the problem is intermittent, the knee may lock or give way periodically. Physical examination reveals tenderness and swelling over the proximal fibula and tibiofibular joint. In the absence of associated injury, findings on knee examination are otherwise normal, with full ROM and no joint line tenderness or effusion.

**Diagnostic Testing**

Plain radiography may confirm the diagnosis, although CT may be required. On the AP view, the fibular head is displaced laterally, and the interosseous space is widened. Comparison views of the uninjured knee may be necessary to appreciate these findings.

**Management**

Traumatic proximal tibiofibular dislocation is treated initially with closed reduction. If the patient seeks treatment within a few days of injury, reduction of an anterolateral dislocation can be accomplished in the ED by flexing the knee to 90 degrees, evertting the ankle, and applying direct pressure to the head of the fibula. Orthopedic referral and immobilization of the knee for a minimum of 3 to 6 weeks are necessary after reduction. If closed reduction fails, the patient may require open reduction, with repair of the torn capsule ligaments and pinning. For recurrent dislocations or injuries that do not respond to initial treatment, resection of the proximal fibula or arthrodesis may be effective.

**Stress Fractures**

**Anatomy and Pathophysiology**

The tibia is a common site of stress fracture. Usually, the stress fracture occurs on the tibial shaft. Fractures typically are horizontal or oblique and uncommonly longitudinal. Other sites of stress fracture include the femur, fibula, tarsals (especially navicular), and metatarsals. Stress fractures result from overuse. Stress fractures, which occur as a result of excessive repetitive force to normal bone, are distinguished from pathologic fractures, which occur as a result of normal forces acting on abnormal bone (eg, because of osteoporosis or tumor).

**Clinical Features**

Bone pain and tenderness without a history of direct trauma are characteristic. The most important historical information includes a recent increase in physical activity, training on hard surfaces, and inadequate footwear. The pain usually is insidious in onset and progressive but may be sudden. Pain is usually relieved with rest. The differential diagnosis for lower leg pain also includes shin splints (see later), exercise-induced compartment syndrome, contusion, muscle strains, tendinitis, periostitis, and interosseous membrane strains. The physical examination may reveal localized bone tenderness and swelling of the underlying soft tissues. Usually, there is no muscle atrophy, weakness, or restriction of joint ROM range of motion and unsuitable.

**Diagnostic Testing**

The radiographic findings vary, depending on the location of the fracture and stage of healing. Approximately one-third of stress fractures are evident radiographically at the time of initial diagnosis, compared with 50% after 2 to 6 weeks. The radiographic findings often are subtle and may include periosteal new bone, sclerosis, and a lucent line perpendicular to the cortex. MRI can diagnose the condition earlier and more accurately than plain film radiography.

If a stress fracture of the lower extremity is suspected and findings on initial plain radiography are unremarkable, follow-up evaluation at 10 days to 2 weeks may detect radiographic signs of fracture after a period of inactivity. Evidence of healing (periosteal reaction) in response to treatment usually is sufficient to confirm the diagnosis.

**Management**

Most tibial and fibula stress fractures can be treated nonoperatively. Activity should be decreased for 3 to 6 weeks to allow for healing, and serial radiographs should be obtained. In those rare cases in which walking causes pain, a cast and non-weight-bearing status may be required. Serial radiographs are used to evaluate healing. Rare cases of nonunion require surgery.

**Compartment Syndrome**

Compartment syndrome is caused by increased pressure within a fascial compartment, leading to necrosis of muscle and nerve, and is discussed in Chapter 49.

**Soft Tissue Injuries Involving the Lower Leg**

**Strains**

Gastrocnemius Strain. The medial head of the gastrocnemius muscle often is strained in sports activities and sometimes ruptures. On physical examination, a palpable gap may be identified in the substance of the muscle, and point tenderness may be elicited in the medial and inferior borders of the muscle belly. Any attempted active or passive ankle dorsiflexion elicits pain.

Gastrocnemius strain or rupture may be confused with the following: rupture of the plantaris tendon, which causes tenderness, swelling, and ecchymosis in the proximal calf; rupture of a Baker’s cyst, which may result in the escape of fluid into the calf; thrombophlebitis; deep venous thrombosis; and Achilles tendon rupture, which typically results in a palpable gap just proximal to the calcaneus. The diagnosis is made clinically, although a soft tissue defect may be seen on plain radiographs of large ruptures. MRI can confirm the diagnosis but is rarely necessary.
A mild partial rupture of the medial head of the gastrocnemius can be treated with rest and non–weight-bearing status for several days. Treatment for more extensive incomplete ruptures involves casting for 8 weeks, with the ankle plantar-flexed. For a complete tear, most orthopedists recommend surgical repair to restore normal length and tensile strength. Acute compartment syndrome can complicate gastrocnemius strain.

**Plantaris Strain and Rupture.** The plantaris is a small variable muscle that originates at the lateral condyle of the femur and passes beneath the soleus to insert on the Achilles tendon. It is a feeble flexor of the knee and plantar flexor of the ankle joint, with little functional significance. Rupture may occur at the myotendinous junction, with or without an associated partial tear of the medial head of the gastrocnemius muscle. A strain of the more proximal plantaris muscle also may occur as an isolated injury or in conjunction with injury to the ACL of the knee. With rupture, the patient often describes a sudden sharp snap sensation—“like I was shot with a ping pong ball”—in the proximal posterior calf, followed by a duller deep ache, which may be disabling. Tenderness is greatest just lateral to the proximal posterior calf, followed by a duller deep ache, which may be disabling. Tenderness is greatest just lateral to the proximal posterior calf. Examination will show intact strength, but pain, with plantar flexion. Treatment is symptomatic, with a posterior splint in partial equinus position for the first few days if pain is severe or assisted walking with a cane in milder cases. The patient should be cautioned that significant posterior calf and posterior ankle ecchymosis often appears over the first few days.

**Shin Splints**

The term *shin splints* refers to anterior tibial pain occurring during or after exercise. The most common causes are a tibial stress reaction or periostitis. Tibial stress reactions are microfractures caused by stress placed on the tibia and are distinct from gross stress fractures, which predispose the affected bone to complete fracture.

The physical examination reveals localized tenderness over the tibia, usually at the junction of the middle and lower thirds. Radiographic studies are not helpful in the diagnosis of shin splints and also cannot exclude a tibial stress fracture with certainty. Treatment is symptomatic—rest, NSAIDs, ice, and supportive footwear. The patient should be referred for outpatient evaluation, during which conservative therapy can be continued or further diagnostic evaluation can be pursued.

**Foreign Bodies**

Foreign bodies such as plant material (eg, thorns) are commonly encountered in the leg. Missed retained foreign bodies in the lower leg can be the cause of cellulitis, abscess, necrotizing fasciitis, and gangrene. Plain films are a necessary part of evaluation but will be unhelpful when the foreign body is radiolucent. Ultrasound imaging is superior for diagnosis and localization; fluoroscopy and MRI are alternatives. Surgical exploration is sometimes necessary. Extraction is difficult, and deep foreign bodies should be removed by a surgeon, often in the operating room.

**KEY CONCEPTS**

- Knee dislocation often causes vascular injury to the popliteal artery. Early revascularization is crucial. Hard signs of vascular injury include absent pedal pulses, cool mottled foot, expanding popliteal hematoma, or popliteal hemorrhage. When any of these are present, angiography or surgical exploration is indicated.
- Soft signs of popliteal artery injury include asymmetric pedal pulses and dorsolateral foot or leg paresthesias. CT angiography or duplex ultrasound study is indicated when these are present.
- In the absence of signs of popliteal injury, the knee dislocation patient can be observed for 24 hours, with measurement of the ankle-brachial index (ABI) every 3 hours. An ABI persistently over 0.9 for 24 hours effectively excludes significant popliteal artery injury.
- Patella dislocation is common, examination reveals the displaced patella fixed in a position superolateral to its normal position, and reduction is by gentle knee extension with medial pressure on the displaced patella. In contrast, in patellar tendon rupture, the patella rides high (patella alta), is not laterally displaced, and is mobile, and the patient is unable to extend the knee.
- Injuries to the cruciate and collateral ligaments may not be detectable on initial examination because of effusion and splinting. Emergent diagnosis is not necessary, but the patient should undergo a follow-up examination by an orthopedist.
- Lipohemarthrosis is an uncommon and subtle sign of occult fracture and should be sought on radiographs of traumatized knees.
- Compartment syndrome is a serious complication of tibial shaft fracture, usually occurring 24 to 48 hours after injury. Orthopedic consultation or measurement of compartment pressure should be undertaken when the patient’s pain is increasing, despite immobilization and support of the fracture.

CHAPTER 50: QUESTIONS & ANSWERS

50.1. A 45-year-old woman presents after a high-impact motor vehicle collision with pain in the left knee. The distal neurovascular examination is intact. What is the most appropriate management?

A. Compression wrap and early range-of-motion exercises
B. Discharge if radiographs are negative with partial weightbearing
C. Knee immobilizer with orthopedic follow-up
D. Measure ankle-brachial index and perform duplex ultrasonography if less than 0.9
E. Orthopedic consultation

Answer: D. This patient had a knee dislocation. Knee dislocation is uncommon but should be considered in the setting of an appropriate injury mechanism because 50% of all knee dislocations are reduced spontaneously before emergency department (ED) arrival. Reduction before ED arrival does not lessen the likelihood of vascular injury, and vascular injury should be considered in patients with severe ligamentous injuries and injuries caused by high-energy mechanisms. Vascular injury to the popliteal artery is the most severe complication and is the major cause of morbidity and limb loss. Management of suspected knee dislocation involves an algorithm designed to be noninvasive but sensitive for arterial injury.

50.2. A 42-year-old man was at the gym performing squatting exercises. As he was coming to a stand, he had an immediate onset of pain in his right thigh. He presents with an inability to extend his knee. What is the most likely physical finding?

A. High-riding patella
B. Midquadiceps muscle tenderness and deformity
C. Popliteal swelling and tenderness
D. Positive Lachman’s test
E. Suprapatellar tenderness with patella baja

Answer: E. This is a quadiceps tendon rupture. Patients with extensor disruption may have signs and symptoms that include an acute onset of pain, swelling, ecchymoses; over the anterior aspect of the knee, a palpable defect in the patella, quadiceps tendon, or patella tendon loss or limited ability for active leg extension; extension lag usually is seen when the last 10 degrees of extension are performed haltingly or with difficulty. With quadiceps rupture, a low-riding patella (patella baja) and inferior retraction may be seen.

50.3. A college football lineman presents complaining of left knee pain and inability to bear weight. He was on the scrimmage line when the ball was placed in motion and, as he lunged forward, he twisted his leg and heard an audible pop in his knee. He was immediately unable to bear weight. On physical examination, you find the left knee swollen, with moderate joint line tenderness and a positive pivot shift test. What is the most sensitive way to diagnose the injury accurately?

A. Arthroscopy of the knee
B. Computed tomography (CT) scan of the knee
C. History and physical examination
D. Magnetic resonance imaging (MRI) of the knee
E. Plain radiography of the knee

Answer: A. Clinical evaluation is moderately sensitive for ACL tears but, in the acute phase, is often inaccurate because of swelling and splinting. Acutely, only plain films are indicated as long as dislocation is not suspected. Tibial plateau fractures detected on plain film may require CT to determine the need for admission for early operative repair. Arthroscopy is the gold standard for diagnosis of soft tissue injuries of the knee. MRI is useful but may miss small tears and anatomic abnormalities, and a normal study may still lead to arthroscopy if symptoms persist. MRI scanning of the knee is rarely indicated in the acute setting.

50.4. A man presents with severe pain of his right lower leg. He was in the ED the previous night for splint placement for a tibial fracture. After removal of the splint, you see a lower leg with mild ecchymosis, healing abrasions, and palpable posterior tibial and dorsalis pedis pulses. He has severe pain on passive movement of his first toe and decreased sensation of the first toe web space. Which of the following should be the next step?

A. Admit for IV antibiotics and pain control.
B. Obtain venous Doppler scans.
C. Resplint the patient.
D. Test the anterior compartment pressures.
E. Test the superficial posterior compartment pressures.

Answer: D. The lower leg is divided into the following compartments by deep partitions of the investing crural fascia—anterolateral, superficial posterior, and deep posterior. The anterior compartment contains the tibialis anterior, long toe extensor muscles, anterior tibial artery, and deep peroneal nerve, which supplies sensation to the first web space of the foot.

50.5. A severe medial ankle sprain with no ankle fracture necessitates evaluation of which of the following?

A. Cervical spine
B. Femoral nerve
C. Lumbar spine
D. Popliteal artery
E. Proximal fibula

Answer: E. An important exception to fibular fractures being stable is a Maisonneuve fracture (see Fig. 50.13). This involves a medial ankle disruption (deltoid ligament tear or medial malleolar fracture), with complete tearing of the syndesmotic ligament joining the tibia and fibula and fracture of the proximal fibula. This results in an unstable ankle mortise because the fibula now floats free relative to the tibia, and surgical fixation is required.

50.6. A 14-year-old boy presents with right knee pain that is worse with physical activity. He has swelling of the inferior aspect of the knee, with point tenderness below the patella, along the patellar tendon, and on the tubercle. Radiographs do not demonstrate a fracture. What is your next step in managing this patient?

A. Admission for repeat serology and physical examinations
B. Discharge if complete blood count (CBC), erythrocyte sedimentation rate (ESR), and C-reactive protein (CRP) level are normal

Answer: B. Discharge if complete blood count (CBC), erythrocyte sedimentation rate (ESR), and C-reactive protein (CRP) level are normal.
C. Emergent orthopedic consultation  
D. Knee brace and crutches  
E. Rest, ice, and pain management  

**Answer: E.** This patient has Osgood-Schlatter disease. Treatment varies according to the acuteness of the symptoms and skeletal age of the patient. Initially, rest, ice, and analgesics are the mainstays of therapy. As symptoms subside, a rehabilitation program that stretches and strengthens the quadriceps should be instituted. Knee orthoses are used to dampen the pull of the extensor mechanism on the weakened tibial apophysis. Immobilization is reserved for the unreliable patient who will not or cannot comply with the program of relative rest in which aggravating activities are avoided.
The ankle and foot are highly evolved structures designed to support the body's weight and facilitate locomotion over varied terrain. Findings related to ankle and foot injuries are often subtle, and diagnoses may be delayed or missed, particularly in cases of multiple trauma.

The ankle and foot are best approached clinically as a single functional unit. Although they are discussed sequentially in this chapter, mechanisms of injury overlap, and a pathologic condition in one location may accompany an associated pathologic condition in another.

### ANKLE PRINCIPLES

#### Anatomy

The ankle joint is the articulation of the tibia and fibula with the talus. The dome of the talus fits into the mortise formed by the medial malleolus, horizontal articular surface of the tibia (plafond), and lateral malleolus. Fundamentally, the stability of the ankle depends on the bony and ligamentous integrity of the mortise. The calcaneus is also important for the motion and stability of the ankle (Figs. 51.1 and 51.2).

The ankle is composed of three primary articulations—the inner surface of the medial malleolus with the medial surface of the talus, distal tibial plafond with the talar dome, and medial surface of the lateral malleolus with the lateral process of the talus. These three articular surfaces are contiguous, lined with cartilage, and enclosed by a single joint capsule. The distalibia also articulates with the distal fibula just proximal to the talus, forming the distal tibiofibular joint. Collectively, these articulations are termed the talocrural joints.

Three sets of ligaments—the syndesmotic ligaments, lateral collateral ligaments, and medial collateral ligaments—support the ankle joint and are essential to its stability.

Tendons course through the ankle in four geographic groups. The flexor retinaculum tethers the tendons of the tibialis posterior, digitorum longus, and flexor hallucis muscles behind the medial malleolus. The peroneal retinaculum and tendon sheath tether the peroneus longus and brevis tendons behind the lateral malleolus. The extensor retinaculum tethers the tendons of the tibialis anterior, extensor digitorum longus, extensor hallucis longus, and peroneus tertius over the anterior aspect of the ankle. Posteriorly, in the midline, lie the Achilles and plantaris tendons.

#### Pathophysiology

Ankle movements are complex and often involve more than one joint. The ankle joint complex is made up of the talocrural joints and talocalcaneal (subtalar) joints, which allow movements along several axes of motion. Dorsiflexion (ankle flexed so the toes point toward the head) and planar flexion (ankle extended so the toes point toward the floor) of the ankle joint complex occur primarily at the talocrural joints. Motions of the ankle joint complex in conjunction with the midtarsal joints include inversion (sole of the foot points to the midline), eversion (sole of the foot points away from the midline), abduction (external rotation of the foot), and adduction (internal rotation of the foot), which are rotational movements about the longitudinal axis of the tibia.

The components providing stability to the ankle are best conceptualized as a ringlike structure surrounding the talus (Fig. 51.3). Disruption of one element of this ring does not, by itself, induce instability. Injury to one ring element, however, should prompt careful scrutiny for a second injury. Any disruption of two or more elements causes ankle instability and can significantly affect joint function.

#### Clinical Features

Carefully eliciting the mechanism of injury can often provide clues as to the injuries sustained. The presence of sudden swelling and severe pain in the ankle region suggests serious ligament disruption, hemorrhrosis, or fracture, and rapid progression of symptoms may represent more severe injury. Inability to bear weight immediately after an injury often implies a significant pathologic condition. Patient recollection of a popping sound should prompt consideration of ligament, tendon, or retinacular rupture but does not necessarily increase the probability of a fracture. Finally, the inciting event causing the ankle injury should be determined and, when necessary, investigated further.

Patients with a subacute or chronic ankle problem may be unable to correlate symptom onset with a particular traumatic event. Inquiry should elicit the type and extent of physical activities and whether the ankle gave way. In older patients, ankle injuries or fractures may manifest as subacute problems reflecting misdiagnosis of a serious condition as a simple sprain or neglect by the patient or caregiver.

#### Physical Examination

The examination of the ankle starts with an assessment of deformity, ecchymosis, edema, and perfusion, followed by active and passive range of motion. Assessment of point tenderness may localize ligament, bone, or tendon injuries, particularly when the patient is seen soon after injury. Palpation should include the medial and lateral collateral ligaments, syndesmotic ligaments, inferior and posterior edges of the medial and lateral malleolus, entire length of the fibula and tibia, anterior plafond, medial and lateral dome of the talus (palpable with the ankle in planar flexion), base of the fifth metatarsal, calcaneus, Achilles tendon, and tendons behind the medial and lateral malleoli. Stress testing of the ankle joint, discussed later, should not be performed until a fracture has been excluded. An evaluation of weight-bearing ability should proceed only if clinical suspicion of a fracture is low, the location of tenderness does not indicate the need for plain radiography, or radiographs have ruled out a fracture. Specific clinical examination tests are discussed elsewhere in the appropriate sections.
Anatomy

- Lateral calcaneus, ligaments, collateral of the disruption of the ankle, medial malleolus, plafond, of stability deltoid ankle.

The lateral view is useful in identifying an ankle effusion, which appears as a teardrop-shaped density displacing the normal fat adjacent to the anterior or posterior margin of the joint capsule. The presence of an effusion suggests the possibility of a subtle intraarticular injury, such as an osteochondral lesion of the talar dome.2

The lateral and mortise views, taken with the ankle in 15 to 25 degrees of internal rotation, are the most important for evaluating the congruity of the articular surface between the dome of the talus and mortise. On the lateral view, any incongruity of the articular space between the talar dome and distal tibia suggests ankle instability, particularly if narrowing of the anterior joint space is present. In the mortise view, the lines formed between the articular surfaces should be parallel, the joint space should appear uniform throughout the tibiotalar and talofibular components of the joint, and the medial clear space should not exceed 4 mm.3

DIAGNOSTIC TESTING

Radiology

The anteroposterior, lateral, and mortise views constitute the standard three-view radiographic series of the ankle. Subtle fractures can be easily missed on ankle radiographs, and a standardized approach to radiographic interpretation can reduce the likelihood of missing ankle fractures (Fig. 51.4).2 The lateral view is useful in identifying an ankle effusion, which appears as a teardrop-shaped density displacing the normal fat adjacent to the anterior or posterior margin of the joint capsule. The presence of an effusion suggests the possibility of a subtle intraarticular injury, such as an osteochondral lesion of the talar dome.2

The lateral and mortise views, taken with the ankle in 15 to 25 degrees of internal rotation, are the most important for evaluating the congruity of the articular surface between the dome of the talus and mortise. On the lateral view, any incongruity of the articular space between the talar dome and distal tibia suggests ankle instability, particularly if narrowing of the anterior joint space is present. In the mortise view, the lines formed between the articular surfaces should be parallel, the joint space should appear uniform throughout the tibiotalar and talofibular components of the joint, and the medial clear space should not exceed 4 mm.3

In most cases of isolated blunt ankle trauma evaluated within 48 hours of injury, the Ottawa Ankle Rules (OAR) should be used to determine whether ankle or foot radiographs are necessary. The OAR state that an ankle radiographic series is required if there is pain in the malleolar region with any of the following findings:

- Bone tenderness at the posterior edge of the distal 6 cm or tip of the lateral malleolus
- Bone tenderness at the posterior edge of the distal 6 cm or tip of the medial malleolus
- Inability to bear weight (defined as the ability to transfer weight onto each leg regardless of limping) for at least four steps immediately after the injury and at the time of evaluation

The OAR further state that a foot radiographic series is required if there is pain in the midfoot region with any of the following findings:

- Bone tenderness at the navicular bone
- Bone tenderness at the base of the fifth metatarsal
- Inability to bear weight for at least four steps immediately after the injury and at the time of evaluation

The OAR have a sensitivity approaching 100% in detecting malleolar zone ankle fractures and midfoot zone fractures. They were derived in an adult population and are not applicable in subacute or chronic injuries. The OAR appear to perform well in pediatric patients older than 5 years, for whom the guidelines can be applied as for adults. In children younger than 5 years, alternative approaches can be used (see Chapter 175).4

The decision rules for foot radiography, although applicable to blunt ankle trauma, apply only to the midfoot zone. The OAR were not designed to be general guidelines for foot radiography and certainly do not apply to the hindfoot or forefoot. Finally, the OAR are not applicable to intoxicated patients or those who are difficult to assess because of head injuries, multiple injuries, or diminished sensation related to neurologic deficits.
Other Imaging Techniques

Although plain radiography is the initial imaging modality of choice for ankle injuries, it can miss subtle ankle fractures, osteochondral lesions, stress fractures, or ligamentous injuries. When unexplained symptoms persist after negative or inconclusive findings on plain radiographs, other imaging modalities or orthopedic consultation may be advisable. In situations where these are unobtainable, the ankle should be immobilized, the patient discharged with instructions to be nonweightbearing, given clear instructions that a fracture may be present despite the lack of conclusive evidence of it on x-ray, and instructed that repeat x-rays or additional imaging may be required on follow-up.

Computed tomography (CT) scanning provides superior bone imaging and is an excellent modality to delineate abnormalities not identified or incompletely characterized by other imaging techniques. This is particularly relevant in the foot and ankle, where x-rays are complicated by overlapping structures and complex articulations. In acute injuries, CT imaging of the foot or ankle is indicated, despite apparently normal radiographs when a fracture is highly suspected.6 The emergency clinician can perform CT in the emergency department (ED) or as part of outpatient follow-up, with the ankle immobilized and nonweightbearing in the interim. CT can detect small fractures, subtle stress fractures, and intraarticular fractures and can facilitate surgical planning. Radionuclide imaging (bone scanning) can detect soft tissue injuries such as distal syndesmotic disruptions, stress fractures, and osteochondral lesions. Bone scan abnormalities are present once a patient is symptomatic; they typically appear 1 to 2 weeks before radiographic evidence of a stress fracture. Because of its high sensitivity, a negative bone scan effectively rules out the diagnosis. Bone scan abnormalities are nonspecific, however, because infections and tumors also can lead to positive results (see later discussion on stress fracture imaging—“Foot”). Bone scanning is not useful for follow-up because abnormalities can persist for up to 1 year after recovery. Radionuclide imaging is virtually always ordered on an outpatient basis and has been largely supplanted by CT and magnetic resonance imaging (MRI).

MRI, although not typically performed emergently, provides unprecedented clarity in depicting soft tissue structures such as ligaments and tendons and can also delineate bone marrow changes associated with stress fractures before radiographic abnormalities appear. MRI can be helpful in guiding management decisions and following the patient’s response to therapy.
MRI or CT arthrography can be useful in the evaluation of chronic ankle pain to detect loose bodies, ligamentous injuries, cartilaginous abnormalities, or osteochondral lesions. CT plus single-photon emission computed tomography (SPECT), which combines CT and radionuclide scanning, has been shown to increase the diagnostic ability of imaging significantly in osteochondral lesions, stress fractures, impingement syndromes, and osteomyelitis. The decision to perform specialized imaging of this nature is typically made through orthopedic or radiologic consultation; such studies are not routinely performed in the ED.

**SPECIFIC PATHOLOGIC CONDITIONS**

**Ankle Fractures: General Considerations**

**Pathophysiology**

Fractures occur when a deforming force is sufficient to overcome the structural strength of a bone. A bone under tension breaks along the axis of the deforming force. Alternatively, ligamentous rupture or an avulsion fracture can occur at either end of a stressed ligament or tendon, and the mechanism of injury generally causes predictable fracture patterns (Fig. 51.6).

**Management**

The management of ankle fractures consists of identification and classification, assessment of stability, emergent reduction of fracture-dislocations that threaten soft tissues or neurovascular status, and specific treatment and disposition.

To date, no ideal system has been developed for the classification of ankle fractures. The Lauge-Hansen classification and Danis-Weber systems are based on mechanism of injury and fracture location, respectively. The Lauge-Hansen classification was intended to characterize ligamentous injury patterns based on the radiographic appearance of ankle fractures but is complex and has been shown to have limitations in broad applicability. The Danis-Weber system (Fig. 51.7) has predictive value for operative repair in isolated lateral malleolar fractures because the location of the fibular fracture is related to the integrity of the syndesmosis. As such, it is more useful to emergency clinicians than the Lauge-Hansen classification. Both systems have limitations, however, and neither accurately predicts management or clinical outcome in all situations. Further details regarding how and when to apply the Danis-Weber system are provided below with the discussion of specific fractures.

The injured ankle should be promptly immobilized, elevated, and iced to minimize swelling and further soft tissue damage. The presence of gross deformity with neurovascular compromise or skin tenting necessitates prompt intervention. Plain radiography before reduction can be helpful but should not delay reduction in injuries with obvious vascular compromise.

In most cases, appropriate procedural sedation and analgesia techniques are required for reduction. The notion that some reductions are accomplished relatively quickly and easily (from the clinician’s vantage point) is not an excuse for failing to adequately manage the often extreme pain that these orthopedic manipulations cause for the patient. The fundamental principle of closed reduction is to reverse the deforming forces. For example, reduction of a fracture-dislocation caused by an adduction injury would require an abduction force. The initial application of a distracting force, sometimes combined with slightly increasing the deformity, is often helpful in achieving reduction. After reduction, neurovascular status should be reassessed, the leg immobilized and elevated, and postreduction radiographs obtained. The overarching goal in the definitive treatment of ankle fractures is to achieve anatomic reduction.

**Disposition**

The outcome of ankle fractures depends on the extent of injuries, number of malleoli fractured, ankle stability, and patient age. In general, all displaced or potentially unstable ankle fractures require orthopedic consultation in the ED (Box 51.1). Extraarticular nondisplaced fractures that disrupt only one ring element generally can be treated with casting for 6 to 8 weeks and involve nonweightbearing with the use of crutches. Orthopedic follow-up on an outpatient basis within 1 to 2 weeks of the injury is ideal if operative intervention is required. The presence of any abnormal measurement on the mortise view (see Fig. 51.5) suggests instability and the need for orthopedic consultation, typically on an urgent outpatient basis. Avulsion fractures, in which the avulsed fragment is smaller than 3 mm in diameter and minimally displaced, can be treated in an identical manner to an ankle sprain.

For ankle fractures that require surgery, the outcome is better in uninimalleolar fractures over trimalleolar fractures, in isolated lateral malleolar fracture over isolated medial malleolar fractures, in multimalleolar fractures without medial malleolar fracture over those with malleolar fractures, and in cases with posterior fragments involving less than one-third of the articular surface over larger fragments.

**Fig. 51.6.** The mechanics of bone failure in rotational tension and types of tension ankle fractures. Arrows indicate the direction of distracting forces. (From Dahners LE: The pathogenesis and treatment of bimalleolar ankle fractures. Instr Course Lect 39:85, 1990.)

**Fig. 51.7.** The Danis-Weber classification of ankle fractures focuses on the location of the fibular fracture in relation to the tibiotalar joint and syndesmosis. Weber A fractures involve inversion-adduction forces. Weber B fractures involve abduction forces. Weber C fractures involve eversion-abduction forces. See text for further explanation. (From Wilson FC: The pathogenesis and treatment of ankle fractures: classification. Instr Course Lect 39:79, 1990.)
Ankle Fractures for Which Orthopedic Consultation in the Emergency Department Is Recommended

**Unimalleolar Fractures**

**Lateral Malleolar Fractures**

Lateral malleolar fractures are the most common ankle fracture. Stability of the ankle joint depends on the location of the fracture in relation to the level of the tibiotalar joint, which defines the distal portion of the syndesmotic ligament. The Danis-Weber classification (see Fig. 51.7) is useful and predictive of outcome in these types of unimalleolar fractures. This classification groups fractures into three types—A, B, and C. Subgroups exist but do not assist the emergency clinician in prognosticating the necessity of operative repair and are beyond the scope of this text. Lateral malleolar fractures below the tibiotalar joint (Danis-Weber type A) rarely disrupt other bony or ligamentous structures and, in the absence of injury to medial structures, such fractures are unlikely to affect the dynamic congruity of the ankle joint. The management of uncomplicated lateral malleolar fractures involves casting for 6 to 8 weeks, with no weightbearing for at least the first 3 weeks and close orthopedic follow-up. Any displacement or concurrent disruption of the lateral components of the ankle warrants orthopedic consultation in the ED for consideration of operative management.

**Medial Malleolar Fractures**

Medial malleolar fractures are usually the result of eversion or external rotation. These two forces exert tension on the deltoid ligament, causing an avulsion of the tip of the medial malleolus or a rupture of the deltoid ligament. Although they can occur in isolation, medial malleolar fractures are commonly associated with lateral or posterior malleolar disruption. Because of this, identification of a medial malleolar fracture warrants a careful examination of the entire length of the fibula for tenderness, the presence of which warrants radiographic evaluation to rule out a proximal fibular fracture (Fig. 51.8).

An isolated nondisplaced medial malleolar fracture can be treated with casting for 6 to 8 weeks, with no weightbearing for at least the first 3 weeks and close orthopedic follow-up. Any displacement or concurrent disruption of the lateral components of the ankle warrants orthopedic consultation in the ED for consideration of operative management.

**Posterior Malleolar Fractures**

Isolated fractures of the posterior malleolus are rare and imply an avulsion of the posterior tibiofibular ligament. These injuries can be associated with proximal fibular fractures and medial and lateral collateral ligament sprains. Treatment usually consists of casting for 6 weeks for nondisplaced fractures in which no associated injury or ankle instability is present. CT is generally used to ensure anatomic reduction prior to conservative management. Fractures involving more than 25% of the tibial surface usually require open reduction and internal fixation (ORIF); however, this is an area of controversy, and displaced posterior malleolar fractures require orthopedics consultation.

**Bimalleolar Fractures**

Bimalleolar fractures involve the disruption of at least two elements of the ankle ring and are therefore unstable. These fractures result from adduction or abduction forces, with the latter being more common. Rotational injuries also can cause bimalleolar fractures, as well as trimalleolar fractures, if the posterior malleolus is involved. Associated damage to other soft tissue structures (eg, the syndesmosis) is common with bimalleolar fractures.

Controversy exists about whether nondisplaced bimalleolar fractures should be treated with surgical or closed reduction, and orthopedic consultation in the ED is warranted. Rarely, stress fractures of the medial malleolus or distal fibula can be seen, particularly in athletes and runners. Plain radiographs may be nondiagnostic, but radionuclide bone scanning, CT, or MRI—the choice is often influenced by local availability—can establish the diagnosis. These injuries can be treated nonoperatively with outpatient orthopedic consultation and follow-up.

**Trimalleolar Fractures**

Trimalleolar fractures involve fractures of the medial, lateral, and posterior malleoli and almost always require surgical fixation.

**Open Fractures**

Open ankle fractures are usually caused by severe isolated ankle injuries or multiple trauma and require emergent orthopedic consultation.

**Management**

After documentation of the neurovascular status and extent of soft tissue trauma, gross contaminants should be removed from...
Pilon Fractures

Pilon fractures involve the distal tibial metaphysis and usually are the result of high-energy mechanisms with axial loading of the ankle joint, such as falls from a significant height. These injuries often are comminuted and associated with significant soft tissue trauma, devastation of joint architecture, and leg shortening. Due to the high-energy mechanism of injury, patients with pilon fractures frequently have other significant injuries.

Pathophysiology

Destot first coined the term hammer fracture to describe how the head of the talus drives itself into the tibial plafond and causes a pilon fracture. The primary deforming force is one of axial compression, and the position of the foot at the time of injury determines the fracture location and pattern. Secondary rotational or shear forces may cause increased comminution and fragment displacement with more extensive soft tissue injuries. One-fourth of pilon fractures are open; associated injuries include fractures of the calcaneus, tibial plateau, femoral neck, acetabulum, and lumbar vertebrae, as well as trauma to other major systems.

Complications

Early operative complications of closed and open ankle fractures include pin site infection, delayed skin necrosis, skin graft rejection, and osteomyelitis. Delayed complications of operative and nonoperative treatment include malunion, nonunion, osteopenia, traumatic arthritis, chronic instability, ossification of the interosseous membrane, avascular necrosis, and complex regional pain syndrome.

Management

Radiographic examination should include the entire tibia and fibula, as well as the ankle. Emergency management principles for open fractures, as outlined previously, should be applied. Treatment involves restoration of the articular surface and fibular length, combined with meticulous management of soft tissue injuries. Because surgical management is required, emergent orthopedic consultation is necessary. Pilon fractures with low-grade soft tissue damage are managed with primary ORIF. In severe pilon fractures with extensive soft tissue damage, however, results are better with a two-stage approach involving initial length restoration and external fixation, followed by anatomic.
Complications

Complications of pilon fractures are common, particularly in more severe cases. Early complications include wound infection, skin sloughing, pin site infection, and wound dehiscence. Delayed and late complications include malunion, nonunion, leg shortening, posttraumatic arthritis, avascular necrosis, and protracted pain. Some patients with severe pilon fractures ultimately require arthrodesis.

**Soft Tissue Injuries**

**Ligament Injuries**

Ankle sprains are commonly seen in EDs and are one of the most common injuries in an active population. Proper diagnosis and rehabilitation are important because 40% of patients experience dysfunction for up to 6 months postinjury. The term ankle sprain refers to a potpourri of ligamentous and nonligamentous injuries. Even when ligamentous injury is certain, the ideal treatment approach is controversial, and there is significant variation in clinical practice.14,15

**Pathophysiology.** Most ankle sprains occur from extreme inversion and planter flexion that produce symptoms on the lateral aspect of the ankle. Usually, the anterior talofibular ligament is injured first, followed by the calcaneofibular ligament if the deforming forces are sufficiently strong (see Fig. 51.1). Approximately two-thirds of ankle sprains are isolated anterior talofibular ligament injuries, whereas 20% involve anterior talofibular and calcaneofibular ligament injuries. In addition, the lateral talocalcaneal ligament may be strained with an inversion injury, leading to avulsion fractures at either end of the attachment sites. Isolated calcaneofibular or posterior talofibular ligament injuries are rare.

Isolated injury of the medially located deltoid ligament occurs in less than 5% of ankle sprains. Rupture of this ligament usually occurs in conjunction with lateral malleolar fractures, especially when an external rotational force is involved.

Injuries of the distal tibiofibular syndesmotic ligaments are uncommon in the general population because of the degree of force required, but represent 10% to 20% of ankle sprain injuries in competitive athletes. Dorsiflexion and external rotation forces are usually responsible for this injury; their presence may significantly prolong the recovery time from concomitant lateral collateral ligament sprains.

Ligamentous injuries are classified into three grades based on functional and presumed pathologic findings, as outlined in Table 51.1. This classification system, although commonly used, fails to characterize ankle injuries involving two or more ligaments and does not address nonligamentous injuries.

**Clinical Features.** Although desirable, an accurate history of ankle position and injury mechanism is often unavailable. Inversion followed by external rotation of the ankle suggests the potential for deltoid or syndesmotic injury. Forced dorsiflexion with snapping may indicate peroneal tendon displacement. On physical examination, the presence of edema, ecchymosis, and point tenderness over the medial or lateral collateral ligaments or syndesmotic ligaments suggests a ligamentous injury. Inability to

                          • Prolonged rehabilitation phase ± delayed surgery |

ATFL, Anterior talofibular ligament; PRICE, protection, rest, ice, compression, elevation; ROM, range of motion.
bear weight in the absence of a fracture suggests the presence of a grade II or III ankle sprain. Deltoid ligament tenderness necessitates palpation of the full length of the fibula to rule out a proximal fibular fracture—type C Danis-Weber or Maisonneuve fracture (see Figs. 51.7 and 51.8). Tenderness should prompt imaging of the entire tibia and fibula.

**Diagnostic Tests and Differential Diagnosis.** The fibular compression test, or squeeze test can be used to diagnose fibular and syndesmotic injuries. To perform this test, the examiner places the fingers over the fibula and the thumb over the tibia; midcalf and squeezes the two bones. Pain anywhere along the length of the fibula suggests a fibular fracture or intersseous membrane or syndesmotic ligament disruption at that location. Finally, the Achilles tendon should be assessed for rupture. Stress testing is the application of a deforming force to assess joint motion beyond the physiologic range; its presence suggests ligament disruption or mechanical instability. Common ankle stress tests include the anterior drawer test, inversion stress test, and external rotation test. The anterior drawer test primarily assesses the integrity of the anterior talofibular ligament. To perform this test, the patient is seated with the knee in 90 degrees of flexion and the ankle in a neutral position or 10 degrees of planar flexion, which is best achieved by allowing the foot to rest along the examiner's wrist and distal forearm, as the examiner cups the heel in his or her hand and gently flexes the ankle to the 90-degree position. The examiner then applies slow but firm traction on the heel with that hand and places the other hand on the anterior tibia to prevent the leg from moving anteriorly. Anterior displacement of the talus, the perception of a “clunk,” and the induction of a sulcus anteromedially over the joint indicate partial or complete tear of the anterior talofibular ligament.

The inversion stress test, or talar tilt test, evaluates the anterior talofibular ligament and calcaneofibular ligament. It is performed by inverting the heel with the knee in 90 degrees of flexion and the ankle in neutral position. Palpation of the head of the talus laterally or a finding of increased laxity compared with the uninjured side suggests partial or complete tear of these ligaments.

The external rotation stress test is indicated when injury to the distal tibiofibular syndesmotic ligaments is suspected. It is performed by externally rotating the foot with the knee in 90 degrees of flexion and the ankle in a neutral position. Pain at the syndesmosis or the sensation of lateral talar motion suggests partial or complete tear of the ligaments.

Stress testing in the ED to identify acute ligamentous disruption is often limited by pain and, to be performed properly, the joint must be anesthetized with local anesthetic. Furthermore, a positive stress test suggesting ligamentous instability rarely alters management in the ED. If needed, this test can be deferred to follow-up.

Standard ankle radiographic views exclude fractures and detect ligamentous instability by allowing the measurement of joint spaces (see earlier discussion and Fig. 51.5). The presence of avulsion fractures constitutes an important clue to the location of ligamentous injuries. Common locations for avulsion fractures include the bases of the malleoli, lateral process of the talus, lateral aspect of the calcaneus, posterior malleolus, lateral aspect of the distal tibia, and base of the fifth metatarsal.

In addition to the standard mortise measurements previously discussed, two measurements on the anteroposterior radiograph further evaluate the distal tibiofibular syndesmosis (see Fig. 51.5). At the distal overlap between the fibula and tibia, the distance between the posterior edge of the lateral tibial groove and medial fibular cortex (syndesmosis A) should not exceed 5 mm. Furthermore, the amount of tibiofibular bony overlap (syndesmosis B) should be at least 10 mm. Measurements outside these values suggest a syndesmotic diastasis. Stress radiographs, accomplished by taking radiographs during stress testing of the ankle, generally do not influence the emergency management of ankle sprains and are not recommended.

Many injuries can masquerade as ankle sprains. Box 51.2 lists conditions to be considered in the differential diagnosis.

**Management.** Most ligament sprains, regardless of severity, heal well and result in a satisfactory outcome. To date, compelling evidence for a significant difference in outcomes between surgical and functional (nonsurgical) treatment is lacking. Most patients with acute sprains of the ankle should start with functional treatment. For the minority who fail to respond, delayed operative repair of ruptured ligaments, sometimes years after the injury, has been shown to yield results equivalent to those with primary repair.

Functional treatment, a form of therapy in which the ankle is not fully immobilized, allowing complete or partial joint function, starts in the ED with PRICE therapy (protection, rest, ice, compression, and elevation). However, significant variability exists in how this combination is applied, and optimal methods for the rehabilitation of ankle sprains remain unclear. The evidence to date suggests that lace-up ankle support is more effective in short-term edema reduction than semirigid ankle support, elastic bandaging, and taping.

For grade I or II injuries, short-term protection with a compression bandage, taping, laced-up support, or commercial brace, with the optional use of crutches for a few days, is appropriate. For patients with first-time ankle sprains, treatment with a lace-up brace combined with elastic wrapping results in an earlier return to function compared with the use of a brace alone, elastic wrap alone, or walking cast.

For severe grade II or grade III injuries, there has been equipoise regarding the merits of immobilization compared with functional rehabilitation, with little high-quality evidence to guide therapy. There is little evidence for a more favorable outcome with complete immobilization over functional treatment incorporating a removable brace, so use of a lace-up support or air cast that permits some ankle motion is preferred. These patients should also use crutches to avoid weightbearing until they can stand and walk a few steps on the injured ankle without pain. Crutch use varies significantly, ranging from a few days to 2 or 3 weeks. Functional therapy allows for the incorporation of earlier physical therapy rehabilitation and quicker recovery.

Discharge instructions are important in ankle sprains. According to evidence-based guidelines, the expected time for return to activity is generally 2 to 4 weeks, depending on the grade of the injury, with more severe injuries requiring a longer return to activity. Patients who have not returned to a normal activity level beyond this time frame should be reevaluated for talar dome injury.
osteochondral lesions, syndesmotic injury, or occult fracture with advanced imaging.\textsuperscript{15,16} Follow-up with the patient’s primary care physician or sports medicine physician is appropriate.

Pain improves with immobilization, but analgesia is usually required. Appropriate analgesia can be provided by systemic nonsteroidal antiinflammatory drugs (NSAIDs), in analgesic doses, or acetaminophen. A short course (2–3 days) of oral opioids is added when pain is severe.\textsuperscript{19}

**Disposition.** Acute ankle ligament sprain rarely, if ever, requires orthopedic consultation in the ED. Primary surgical repair of acute ligament rupture is controversial; possible indications include sprains with displaced osteochondral lesions, complete tears of the anterior talofibular and calcaneofibular ligaments in a young athlete, a ligament sprain associated with a fracture causing instability (eg, a deltoid ligament rupture with a lateral malleolar fracture), and an acute severe sprain in a patient with a history of recurrent and severe sprains.\textsuperscript{17} Failure of nonoperative treatment also constitutes an indication for surgical repair; however, an orthopedic referral on an outpatient basis is adequate ED management.\textsuperscript{17}

Small avulsion fractures of the fibula or tibia with minimal or no displacement can be treated in the same manner as an ankle sprain. If the avulsed fragment is larger than 3 mm or significantly displaced, splinting and referral for orthopedic follow-up on an outpatient basis are justified.

as in a runner accelerating from the starting position. Factors predisposing to Achilles tendon rupture include preexisting disease such as rheumatoid arthritis, systemic lupus erythematosus, gout, hyperparathyroidism, chronic renal failure, steroid use or injection, fluoroquinolone antibiotic therapy, and previous Achilles tendon rupture. The vast majority of ruptures, however, occur spontaneously during activity or trauma, without risk factors other than being male and advancing age.

The diagnosis of Achilles tendon rupture is primarily clinical. Patients usually describe a sudden onset of pain at the back of the ankle associated with an audible pop or snap. Although the pain can resolve rapidly, weakness in plantar flexion persists. On examination, a visible and palpable tendon defect may be noted 2 to 6 cm proximal to the calcaneal insertion in acute presentations but will be less apparent in delayed presentations because of hematoma or edema. Even in cases of complete Achilles tendon rupture, weak plantar flexion may still be possible because of the actions of the tibialis posterior, toe flexors, and peroneal muscles. This retained ability for plantar flexion leads to the misdiagnosis of complete ruptures as ankle strains or partial tears in as many as 25% of cases.

The classic maneuver to assess the integrity of the Achilles tendon is the Thompson test. This is performed with the patient prone and the knee flexed at 90 degrees or the feet hanging over the end of the stretcher. Alternatively, the patient kneels on a chair with both knees flexed at 90 degrees and the feet hanging over the edge. With an intact Achilles, squeezing the calf muscles in these two positions should cause passive plantar flexion of the foot. Absence of this motion, or a markedly weakened response compared with the uninjured side, suggests complete rupture. Lateral radiographic views of the ankle may suggest rupture by showing opacification of the fatty tissue—filled space anterior to the Achilles tendon (Kager’s triangle) or an irregular contour and thickening of the tendon. Ultrasonography or MRI can demonstrate partial or complete tendon ruptures, but these studies are indicated only when diagnostic uncertainty exists.

A lack of consensus exists between operative and nonoperative management in the treatment of Achilles tendon rupture. Surgical repair is routinely performed in active individuals owing to its lower incidence of rerupture. However, surgery carries higher rates of other complications, such as superficial or deep wound infections, in comparison with nonoperative management. In both types of management, early mobilization improves functional recovery without increasing rerupture rates. Achilles tendon rerupture after initial nonoperative treatment usually necessitates surgical repair. Orthopedic referral of patients with Achilles tendon rupture is necessary to determine the appropriate management. Regardless, on discharge from the ED, for surgical or conservative management, the patient is placed in a walking boot with maximal heel lift or posterior slab with the foot plantarflexed in full equinus.

**Peroneal Tendon Dislocation or Rupture.** The peroneal muscles are the primary evertors and pronators of the foot and also participate in plantar flexion. The peroneus longus and brevis tendons use the posterior peroneal sulcus (the fibular groove), located behind and underneath the lateral malleolus, as a pulley for their midfoot insertions. The peroneus brevis tendon inserts onto the tuberosity of the fifth metatarsal, and the peroneus longus tendon courses beneath the cuboid to insert onto the medial cuneiform and base of the first metatarsal. The superior peroneal retinaculum (Fig. 51.10), a fibrous structure running from the distal fibula to the posterolateral aspect of the calcaneus, maintains the peroneal tendons against the fibular groove and, when ruptured, causes dislocation of the peroneal tendons. Injuries of the peroneal tendons include chronic overuse tendinopathy, tendon rupture, and tendon dislocation.

**Tibialis Posterior Tendon Rupture.** The tibialis posterior is primarily responsible for plantar flexion and inversion along the subtalar joint. Its tendon uses the posteroinferior surface of the medial malleolus as a pulley and inserts onto the navicular, medial cuneiforms, and bases of the second through fifth metatarsals. The peroneus brevis opposes the action of the tibialis posterior. With rupture of the tibialis posterior tendon, the peroneus brevis becomes unopposed, and the medial longitudinal arch loses its muscular support, leading to valgus deformity of the hindfoot and a unilateral flatfoot.

The mechanism of traumatic tibialis posterior rupture involves forced eversion. In addition to a unilateral flatfoot, pain and swelling on the medial aspect of the ankle are seen. Tenderness is present over the navicular, and the patient cannot perform a toe raise on the affected side. The patient with a tibialis posterior tendon rupture is also unable to invert the foot when it is in plantar flexion and eversion. With a unilateral flatfoot, an observer standing behind the patient can see more toes on the lateral aspect of the affected side—a classic sign of tibial posterior rupture. Plain radiography can exclude other bony abnormalities. Outpatient orthopedic consultation is indicated for tibialis posterior tendon ruptures because surgical repair often is necessary.

**Other Tendon Injuries.** Injuries to the other tendons of the ankle are relatively rare and are outlined in Table 51.2. The tibialis anterior tendon is the primary dorsiflexor of the foot. It courses under the superior extensor retinaculum anterior to the medial malleolus and inserts onto the navicular, medial cuneiform, and base of the first metatarsal. The flexor hallucis longus tendon is responsible for flexion of the great toe and participates in plantar flexion of the foot. It courses behind the medial malleolus through a fibro-osseous canal and travels along the undersurface of the foot to insert onto the distal phalanx of the great toe. The extensor hallucis longus tendon travels anteriorly through the superior extensor retinaculum and inserts on the dorsal surface of the base of the distal phalanx of the hallux.
dislocations can occur without fracture. The mechanism in all dislocations begins with axial loading of a plantar-flexed foot, which forces the talus anteriorly or posteriorly from the ankle mortise. The eventual position of the dislocation depends on the position of the foot at the time of injury and direction of the displacing force. Ankle dislocations can be closed or open and usually result from significant falls, motor vehicle collisions (MVCs), or high-speed sports. The neuromuscular supply to the foot usually is intact but may be compromised in open dislocations.

ED management involves the assessment of neuromuscular status and tendon function, followed by rapid reduction. Radiographs are helpful but should not delay reduction when vascular compromise or skin tenting is present. After appropriate procedural sedation or hematoma block, the patient is placed supine, and the knee is flexed to 90 degrees. Distraction of the foot, followed by a gentle force to reverse the direction of the dislocation, usually accomplishes the reduction. Reassessing the neuromuscular status, splint immobilization, ankle elevation, and post-reduction radiography should follow. Open dislocations require the same management as previously discussed for open fractures. The prognosis for an ankle dislocation is usually good, although open fractures are associated with an increased incidence of complications.

FOOT

PRINCIPLES OF DISEASE

Anatomy

The foot is composed of 28 bones and 57 articulations (Fig. 51.11), which can be divided into three anatomic and functional regions—the hindfoot, containing the talus and calcaneus; the midfoot, consisting of the navicular, cuboid, and cuneiforms; and the forefoot, which includes the metatarsals, phalanges, and sesamoids. The midtarsal, or Chopart’s joint, connects the hindfoot to the midfoot, and the tarsometatarsal, or Lisfranc’s joint, connects the midfoot and forefoot. The subtalar joint, comprised of three articulations between the talus and calcaneus, is another clinically important joint. Inversion and eversion of the hindfoot occur primarily through the subtalar joint, adduction and abduction of the forefoot through the midtarsal joints, and flexion and extension through the metatarsophalangeal (MTP) and interphalangeal (IP) joints.

The bones of the foot interlock to form a complex system of arches and beams tethered by ligaments and intrinsic muscles. Extrinsic muscles originating in the lower leg are responsible for most of the foot’s movements. The course and insertion of these extrinsic muscles are important in their actions and association with specific avulsions and injuries. The arterial supply to the foot is from the anterior and posterior tibial arteries and peroneal artery, a proximal branch of the posterior tibial artery. Motor and sensory innervation comes from branches of the deep and superficial peroneal, posterior tibial, saphenous, and sural nerves.

Clinical Features

In the setting of foot injury, an accurate history is essential, paying particular attention to the mechanism of injury, timing, and duration of symptoms. The location of pain, along with a description of its quality, duration, and precipitants, focuses the differential diagnosis. A history of underlying medical conditions, medications, and previous foot problems is important in certain clinical contexts.

A directed examination specific for the patient’s complaint is most useful in the ED. The physical examination of the foot begins, if possible, with observation of gait and proceeds with assessment of the foot in its position of rest, normally one of slight plantar flexion and inversion. Swelling, deformity, ecchymosis, open wounds, color, and temperature should be noted. Precise localization of pain or crepitus, when not precluded by swelling, is extremely valuable and facilitates appropriate use of further diagnostic tools. The entire foot should be methodically palpated, paying particular attention to commonly injured areas. Complete assessment includes a detailed neuromuscular examination.

In some situations, an evaluation of active and passive range of motion is indicated. Subtalar motion is evaluated by holding the lower leg with one hand and the heel with the other. Then, with the foot in a neutral position, the heel is inverted and everted. There is a substantial variability in range, with normal being 5 to

Fig. 51.11. Bones and joints of the foot. (From Rockwood CA, Green DP, Bucholz RW, editors: Rockwood and Green’s fractures in adults, ed 3, New York, 1991, JB Lippincott.)
20 degrees of eversion and 5 to 40 degrees of inversion.24,25 Midtarsal motion is evaluated by stabilizing the heel while the other hand grasps the forefoot. There should be at least 20 degrees of adduction and 10 degrees of abduction.

Forefoot motion is evaluated by flexing and extending the MTP and IP joints individually. The first MTP joint has a particularly wide passive range of motion, with 45 degrees of flexion and 70 to 90 degrees of extension. Throughout the physical examination, findings can be compared with those of the opposite foot.

Diagnostic Testing: Radiology

Standard three-view radiographs of the foot consist of anteroposterior, lateral, and oblique projections. The lateral gives the best imaging of the hindfoot and soft tissues, whereas the anteroposterior and oblique projections give the best imaging of the midfoot and forefoot. The overlapping bones of the foot demand this complete radiographic series when radiographic examination is indicated. Injuries to the hindfoot may warrant the addition of ankle projections and, when indicated, calcaneus views.

Foot radiographs can be difficult to interpret. Moreover, foot fractures are often minimally displaced or nondisplaced, increasing the challenge of radiographic diagnosis. In certain cases, specialized views may improve the imaging of specific areas of the foot. Although largely supplanted by the use of CT, certain views may be of particular clinical value. This is the case for stress or weight-bearing views in suspected Lisfranc injuries.

Accessory ossification centers, found in 30% of the population, can complicate interpretation of plain radiographs. These accessory bones are differentiated from fractures by their smooth corticated surfaces and with comparison radiographs of the opposite foot, although such variants are not inevitably bilateral. The most commonly seen accessory bones are the os trigonum, os tibiale externum (also called an accessory navicular bone), os peroneum, and os valesianum.26 Accessory bones themselves can also fracture or cause pain syndromes.

Plain radiography has limitations in the assessment of foot and ankle injuries. In the foot, overlapping bones and complex articulations can make plain radiography difficult to interpret. CT is valuable for imaging the midfoot, calcaneus, subtalar joint and tarsometatarsal (Lisfranc) joint complex.

Advanced imaging, including MRI, ultrasound, and bone scanning, are useful for the diagnosis of foot injuries. However, these tests are rarely indicated in the ED and are often best arranged following consultation with orthopedic, sports medicine, or radiology specialists.

MRI is useful for the diagnosis of ligamentous injury and soft tissue injury but also has value for identifying stress fractures and cartilaginous injury, such as talar dome osteochondral lesions.27,28 A common indication for MRI in foot injury would be the diagnosis of a low-energy, or ligamentous, Lisfranc injury. In the case of stress fractures, MRI has comparable sensitivity and better specificity than bone scanning and has emerged as the imaging modality of choice for this diagnosis.29

Radionuclide imaging (bone scanning) can be useful for evaluating unexplained foot pain or pain in athletic injuries. CT-SPECT overlays bone scanning with more detailed anatomic information provided by CT imaging to improve localization of lesions. This specialized technique is useful in the diagnostic algorithm for a number of foot disorders, including osteochondral lesions, stress fractures, and osteomyelitis.30,31

SPECIFIC PATHOLOGIC CONDITIONS

This section covers the major fractures and dislocations seen in the foot, progressing anatomically from the hindfoot through to the forefoot.

Hindfoot Injuries

The hindfoot is commonly involved in foot injuries and is a difficult area to image. Fractures or dislocations in this region can masquerade as ankle sprains and can be easily missed.

Talar Fractures

Principles of Disease: Anatomy. The talus is divided into three regions—the head, which articulates with the navicular and calcaneus; the body, which articulates with the tibia, fibula, and calcaneus; and the neck, which connects the head and body. The neck is the only region that is predominantly extraarticular. The talus has seven articulations making up 60% of its surface, has no muscular attachments, and is held in position by the malleoli and ligamentous attachment. The anterior width of the talus is greater than the posterior, causing it to be less stable and more prone to dislocation when the foot is plantar-flexed.

The blood supply to the talus is from a vascular ring formed by branches of the anterior and posterior tibial arteries and perforating branch of the peroneal artery. Vessels enter from three sites, all of which can be disrupted by fractures or dislocations, putting the talus at risk of avascular necrosis.

Pathophysiology. Talar fractures are described by anatomic region and are grouped into minor and major fractures, with minor fractures being the more common.

Minor Talar Fractures. These include avulsion fractures of the superior neck and head and lateral, medial, and posterior aspects of the body. These fractures often involve the same mechanism as ankle sprains (see Box 51.2), a combination of plantar flexion or dorsiflexion and an inversion force. Lateral process fractures result from forced dorsiflexion. These fractures, which can be occult on plain radiographs, have been most commonly described in snowboarding, but do occur in other sports, as well as MVCs.32-34 Osteochondral lesions of the talar dome, which also fall into the minor fracture category, can cause significant morbidity.

Major Talar Fractures. These are high-energy fractures that occur in the head, neck, or body. Talar head fractures make up 5% to 10% of all talar fractures.35 Their mechanism is a compressive force applied on a plantar-flexed foot and transmitted up through the talonavicular joint. Commination is common, and associated navicular fractures can occur, further disrupting the talonavicular articulation.

Talar neck fractures account for 50% of major talar injuries.35 Their mechanism usually is an extreme dorsiflexion force, as generated in falls or MVCs. Associated fractures are common, usually an oblique or vertical fracture of the medial malleolus. Other associated injuries include calcaneal fractures and vertebral compression fractures.

The Hawkins classification grades talar neck fractures by displacement and associated subluxations (Fig. 51.12):

• Type 1 fractures are nondisplaced.
• Type 2 fractures are displaced vertical fractures, with subtalar joint subluxation.
• Type 3 fractures, 50% of which are open, involve a vertical talar neck fracture, with subluxation of the subtalar and tibiotalar joints.
• Type 4 fractures, which are uncommon, involve distraction of the subtalar, tibiotalar, and talonavicular joints.

This classification system guides treatment and correlates with the incidence of avascular necrosis (AVN) which can approach 50% for type 3 fractures. Posttraumatic arthritis has been reported in up to 75% of patients following talar neck fractures.36,37

Talar body fractures include many of the minor talar fractures previously listed. Major talar body fractures are uncommon and
Nondisplaced minor talar fractures are treated with casting. Depending on the degree of swelling and follow-up plans, patients should be non-weightbearing, with a below-knee cast or posterior plaster slab. Displaced or comminuted lateral process fractures require operative fixation because of their articular involvement. Minor fractures with fragments larger than 5 mm in diameter may require excision.

Talar neck fractures carry a significant risk of long-term morbidity and require precise reduction. Type 1 fractures, which are nondisplaced, are the only talar neck fractures amenable to non-operative treatment, which initially consists of 6 weeks of non-weightbearing in a cast. Close outpatient orthopedic follow-up is essential. Hawkins types 2 to 4 fractures or talar neck fractures with any displacement are managed surgically. Significantly displaced fractures, particularly if associated with neurovascular or cutaneous compromise, require an emergent attempt at closed reduction in the ED.

The treatment of talar head and body fractures is controversial and requires emergent orthopedic consultation. Displaced fractures, or those involving a significant degree of articular surface, should be managed surgically. Nondisplaced fractures of the talar body may require surgical management due to the large articular surface requiring precise anatomic alignment. However, some

usually result from falls with axial compression of the talus between the tibial plafond and calcaneus. These fractures are typically intraarticular, involving the ankle and subtalar joints.

Clinical Features. Talar fractures range from obvious open fractures to subtle injuries requiring special imaging for diagnosis. Typically, a history of a twisting injury, fall, or high-energy impact can be elicited. Dorsal swelling and tenderness over the talus are characteristic findings. Although ankle motion may be preserved, inversion and eversion of the hindfoot often are painful.

Diagnostic Testing: Radiology. With minor talar fractures, plain radiographs can be misinterpreted as normal, and CT may be required when clinical suspicion is high. Standard foot and ankle radiographs usually demonstrate major talar fractures (Figs. 51.13 and 51.14), with anterior and oblique projections showing talar alignment within the mortise and the lateral projection showing the talar neck and alignment of the posterior aspect of the subtalar joint. In the case of major talar fractures and intraarticular fractures, routine CT scanning is recommended. Plain radiographs have a sensitivity of only 74% and may underestimate fracture severity, particularly with respect to the degree of articular involvement. CT improves the reliability of classification and provides additional information in 93% of talar fractures.

Management. Nondisplaced minor talar fractures are treated with casting. Depending on the degree of swelling and follow-up plans, patients should be non-weightbearing, with a below-knee cast or posterior plaster slab. Displaced or comminuted lateral process fractures require operative fixation because of their articular involvement. Minor fractures with fragments larger than 5 mm in diameter may require excision.

Talar neck fractures carry a significant risk of long-term morbidity and require precise reduction. Type 1 fractures, which are nondisplaced, are the only talar neck fractures amenable to non-operative treatment, which initially consists of 6 weeks of non-weightbearing in a cast. Close outpatient orthopedic follow-up is essential. Hawkins types 2 to 4 fractures or talar neck fractures with any displacement are managed surgically. Significantly displaced fractures, particularly if associated with neurovascular or cutaneous compromise, require an emergent attempt at closed reduction in the ED.

The treatment of talar head and body fractures is controversial and requires emergent orthopedic consultation. Displaced fractures, or those involving a significant degree of articular surface, should be managed surgically. Nondisplaced fractures of the talar body may require surgical management due to the large articular surface requiring precise anatomic alignment. However, some
have advocated for the treatment of nondisplaced talar body fractures with a cast and nonweightbearing.\textsuperscript{35,40}

**Disposition.** All patients with talar fractures should be followed by orthopedics. Minor fractures that are nondisplaced are suitable for outpatient referral. Displaced or comminuted minor fractures such as lateral process fractures can be splinted for urgent orthopedic evaluation in 1 to 2 days.

Patients with major talus fractures should have an emergent orthopedic evaluation. These fractures have a high incidence of complications, the most significant of which is avascular necrosis.\textsuperscript{36,37} The outcome depends on the degree of anatomic reduction attained and preservation of the vascular supply. Other potential complications include skin infection, skin necrosis, posttraumatic arthritis, malunion, delayed union, nonunion, and predisposition to peroneal tendon dislocation.

**Osteochondral Lesions**

Osteochondral lesions of the talar dome warrant special mention. These talar body injuries describe defects of the articular cartilage and often include subchondral bone.\textsuperscript{35} The mechanisms of injury are identical to those causing ankle sprains and fractures. Although limited data exist, osteochondral lesions may complicate up to 50% of ankle sprains and 70% of ankle fractures.\textsuperscript{41,42} Osteochondral lesions are graded from 1 to 4, according to the progressive depth of the lesion.

An osteochondral lesion should be considered in any patient with acute ligamentous ankle injury accompanied by gross edema and an effusion visible on plain radiographs. However, most osteochondral lesions are not diagnosed at the time of injury but present as persistent pain and effusions (see Box 51.2). Physical findings usually are nonspecific, although tenderness over the posteromedial talus and increasing pain with exertion, weightbearing, or passive plantar flexion may be noted. Standard view radiographs are commonly normal in appearance or show subtle and easily overlooked abnormalities (Fig 51.15). Bone scanning has historically been advocated as a screening modality, but its role has been supplanted by MRI, CT-SPECT, or CT. MRI has emerged as the imaging modality of choice for osteochondral lesions owing to its ability to detect bone marrow edema and cartilaginous defects.

The natural history of osteochondral lesions is poorly defined and variable; however, chronic ankle discomfort and osteoarthritis are potential sequelae. When an osteochondral lesion is confirmed or suspected, patients should be referred for outpatient consultation with an orthopedic specialist. Low-grade and minimally symptomatic lesions are amenable to a trial of conservative therapy in a protective boot. Although there are many management options, higher grade lesions are often managed surgically. Patients with higher grade symptomatic lesions should be made nonweightbearing and can be placed in a splint for comfort.

This discussion underscores the importance of detailed discharge instructions following diagnosis of an ankle sprain. Patients with persistent swelling and pain or inability to return to function beyond the expected 2 to 4 weeks should be advised to seek follow-up with a primary care physician.

**Subtalar Dislocations**

**Principles of Disease: Pathophysiology.** Subtalar dislocation, also called peritalar dislocation, is the simultaneous
disruption of the talocalcaneal and talonavicular joints, without
disruption of the tibiotalar joint. This occurs when the talonavicu-
lar and talocalcaneal ligaments rupture while the stronger calca-
neonavicular ligament remains intact. Subtalar dislocations are
rare and are classified by the direction that the foot takes in rela-
tion to the talus. Medial dislocations are most common, with
lateral, anterior or posterior occurring rarely. Of subtalar disloca-
tions, 10% are open, and associated fractures are present in 50%
of cases, particularly those with lateral dislocations. Dislocation
of the calcaneus is an exceptionally rare event distinct from sub-
talar dislocation; it involves disruption of the talocalcaneal and
calcaneocuboid articulations.

Clinical Features. Obvious deformity typically is present,
often with skin tension on the side opposite the direction of dis-
location. Neurovascular status should be carefully assessed,
although it is rarely compromised. Swelling can mask the extent
of the injury; thus, diagnosis can be delayed or missed if only
ankle radiographs are obtained.

Diagnostic Testing: Radiology. Although standard foot
radiographic views are diagnostic, properly positioning the patient
for them may be difficult. The single most helpful radiograph is
an anteroposterior view of the foot, which will demonstrate the
talonavicular dislocation.

Management. Subtalar dislocations require expeditious
reduction. Most closed subtalar dislocations can be treated with
closed reduction, with procedural sedation in the ED or general
anesthesia. Closed reduction is performed by flexing the knee
and applying longitudinal traction to the foot with initial accen-
tuation, followed by reversal of the deformity, using evasion
for medial dislocations and inversion for lateral dislocations.
Sometimes, direct pressure over the head of the talus aids in
reduction. Closed reduction may be impossible because of but-
tonholing of the talus through the extensor retinaculum, entrapment
in the peroneal tendons, or associated fractures. After
reduction, immobilization in a below-knee cast for 4 to 6 weeks
is indicated.

Disposition. Emergent orthopedic consultation is indicated
for subtalar dislocations. Although serious complications, such as
AVN, are uncommon in cases of closed subtalar dislocation, most
patients have long-term limitation of subtalar motion, a sequela
that can affect gait.

Total Talar Dislocation

Total talar dislocation is an extremely rare and devastating
injury requiring orthopedic consultation in the ED. In these
injuries, which are the end result of the same forces that produce
subtalar dislocation, the entire talus is distracted from all its
articulations. Most are open, and infection and AVN are common
complications.

Calcaneal Fractures

Principles of Disease: Anatomy. The calcaneus is the
largest and most commonly fractured tarsal bone. It articulates
superiorly with the talus (forming the subtalar joint) and antero-
laterally with the cuboid.

Pathophysiology. Calcaneal fractures are often high-energy
injuries with serious short- and long-term consequences. They are
most common in younger males, occurring frequently as a result
of a fall from a height. Multisystem injury has been noted in 5%
and spinal injury in approximately 6% of patients with calcaneal
fractures. Up to 5% are open fractures, and compartment syn-
drome occurs in up to 10% of calcaneal fractures. Frequently,
the diagnosis of compartment syndrome is made late, only after
the development of complications. Other common complica-
tions include infection, chronic heel pain, posttraumatic arthritis,
and hindfoot deformity. Inability to return to work or wear
normal shoes are also common complications. Despite
the association with high-energy injuries, other mechanisms may
cause calcaneal fractures, including simple falls from standing
height, particularly in older women. Calcaneal fractures are
classified as intraarticular, which involve the subtalar joint, or
extraarticular.

Intraarticular Calcaneal Fractures. These are more common
and more serious, accounting for up to 75% of calcaneal fractures.
Classification systems used to describe intraarticular fractures are
complex and more relevant to surgical consultants for planning
and prognosis. The commonly used classification systems have
suffered poor interobserver reliability although, with CT scan-
ing, reliability has improved.

Extraarticular Calcaneal Fractures. These do not involve
the posterior articular surface. They include fractures of the
anterior process, sustentaculum tali, lateral and medial calcaneal
processes, peroneal tubercle, and tuberosity and extraarticular
fractures of the calcaneal body. Isolated calcaneal tuberosity
fractures occur as a result of avulsion by the Achilles tendons and
are rare. These fractures can be serious in that displacement can
compromise the skin overlying the Achilles tendon.

Clinical Features. Physical examination reveals pain, swell-
ing, and tenderness over the heel. Weightbearing on the hindfoot
is usually impossible. Ecchymosis may extend over the entire sole,
and the heel may appear deformed, shortened, widened, or tilted.
Particular attention should be given to the assessment of compart-
ment syndrome, as well as to tension in overlying skin.

Diagnostic Testing: Radiology. In the case of a suspected
calcaneal fracture, initial radiographic imaging should include
a foot series with the addition of a Harris, or axial calcaneal,
view. The anteroposterior view shows the calcaneocuboid joint
and anterosuperior calcaneus, whereas the lateral view shows
the posterior facet and can demonstrate compression of the cal-
caneal body. The Harris view is an additional axial projection
of the calcaneal tuberosity, subtalar, and sustentaculotalar joints
(Fig. 51.16).

Two assessments are critical to the management of calcaneal
fractures—determining whether the fracture involves the subtalar
joint and the degree of depression of the posterior facet. Compre-
sion fractures are not always obvious, and measurement of Boe-
lner’s angle (Fig. 51.17) can be helpful in making the diagnosis.
However, the prognostic value of Boehler’s angle is controversial.
Recent evidence has suggested that determining the preoperative
Boehler’s angle is predictive of injury severity, but only the post-
operative angle is predictive of functional outcome. Findings on
x-ray can be subtle. CT scanning can be provide valuable information for prognosis and treatment planning.

When an intraarticular fracture is identified on plain film, or is
clinically suspected, a CT scan should be performed.

Management. The decision to manage intraarticular or
displaced calcaneal fractures operatively or conservatively must be
made in consultation with an orthopedic surgeon. Recent reviews
have provided conflicting results regarding the functional outcome
of operatively and nonoperatively managed calcaneal fractures.
Operative repair is indicated for open fractures, as well as those
with neurovascular, skin, and soft tissue compromise. The treat-
ment of nondisplaced extraarticular fractures usually involves
casting for 6 to 8 weeks.
Midtarsal Joint Injuries

The midtarsal joint (Chopart’s joint) is composed of the talonavicular and calcaneocuboid joints. Injury in this area can occur with any ankle, hindfoot, or midfoot trauma. Midtarsal joint injuries usually result from forced dorsiflexion and often are associated with other fractures. Sprains, fracture-subluxations and fracture-dislocations, and an isolated so-called swivel dislocation (a variant of a subtalar dislocation) all can occur at the midtarsal joint. Pain, swelling, inability to bear weight, and tenderness over the midtarsal joint are usual findings. Although standard radiographs often are abnormal in appearance, the diagnosis frequently is overlooked or delayed, with symptoms ascribed to an ankle sprain (see Box 51.2). The possibility of a midtarsal joint injury should be considered with any isolated midfoot fracture, particularly those of the navicular tuberosity. MRI can be helpful in the evaluation of midfoot tendon and ligamentous injuries, although rarely indicated in the ED. Nondisplaced injuries may heal with casting, but operative fixation is often required, and management can be difficult. Complications are common and include persistent pain, arthritis, and long-term disability. Patients with a clinically suspected midtarsal joint injury should be made nonweightbearing, with specialist follow-up for repeat assessment and arrangements made for advanced imaging, if indicated.

Midfoot Injuries

The midfoot is an inherently stable region of the foot and is not commonly injured. Fractures and relationships of the midfoot tarsals are difficult to visualize on standard radiographic views. A compounding factor is that pain associated with midfoot injuries may be ill-defined and poorly localized. Although isolated fractures of the midfoot tarsals occur, associated injuries, including metatarsal fractures, subluxations, and spontaneously reduced tarsometatarsal dislocations, may be present.

Navicular Fractures

Principles of Disease: Anatomy. The navicular forms the supporting structure for the medial arch of the foot and bears most of the load within the tarsal complex during weightbearing. Because of the navicular’s extensive articular surface, its blood supply enters only through a small waist of cortex, leaving most of the load within the tarsal complex during weightbearing.
Pathophysiology. Navicular fractures are classified as dorsal avulsion fractures, tuberosity fractures, and body fractures. Stress fractures of the navicular, although uncommon, carry a high risk of morbidity related to misdiagnosis and subsequent fracture with nonunion.

Clinical Features. Navicular fractures cause localized tenderness over the dorsal and medial aspects of the midfoot. The navicular tuberosity is palpated anterior to the sustentaculum tali, a shelf of bone on the medial ankle approximately 2.5 cm below the tip of the medial malleolus. In the case of tuberosity fractures, pain may be exacerbated by passive eversion or active inversion of the foot.

Diagnostic Testing: Radiology. Although standard foot radiographs usually identify navicular fractures, advanced imaging with CT may be necessary. This is particularly the case for patients with high-energy or complex foot injuries, for which the sensitivity of plain radiography is poor. It is not uncommon to confuse the os tibiale externum, also called an accessory navicular bone, with an acute fracture.

Management. Nondisplaced dorsal avulsion, tuberosity, and body fractures are treated in a walking cast for 4 to 6 weeks. Decisions regarding treatment of displaced body fractures, as well as dorsal avulsion fractures involving more than 25% of the talonavicular joint, should be made in consultation with orthopedics. These fractures may be operatively managed and can carry a significant risk of long-term complications and functional limitation.

Disposition. Most navicular fractures are suitable for outpatient orthopedic referral. Unless a significant amount of articular surface is involved, dorsal avulsion fractures can be treated with a compressive dressing and symptomatic management. Significant fractures, particularly if intraarticular, warrant orthopedic consultation in the ED. Navicular tuberosity fractures can be complicated by nonunion. AVN and arthritis are potential late sequelae.

Cuboid Fractures

Cuboid fractures usually occur with other midfoot fractures, including Lisfranc injuries. Fractures are generally the result of avulsion or crush injury. The latter, known as a nutcracker fracture, results from compression of the cuboid between the bases of the fourth and fifth metatarsals and calcaneus. They are also associated with fractures of the posterior malleolus.

The cuboid is best evaluated by the oblique view of a standard foot radiographic series because this demonstrates the calcaneocuboid and cuboid-metatarsal relationship. The possibility of Lisfranc’s injury should be considered with any cuboid fracture. Treatment of isolated injuries ranges from casting for minor nondisplaced fractures to operative fixation. Nondisplaced cuboid fractures are suitable for urgent outpatient orthopedic follow-up. A compressive dressing and splint are reasonable in the interim prior to consultation. Cuboid fractures associated with more significant injury or other fractures should have orthopedic consultation in the ED. Extraarticular cuboid fractures can be complicated by disruption of the peroneus longus tendon at the level of the peroneal groove.

Cuneiform Fractures

Fractures of the cuneiforms are extremely uncommon and usually result from direct trauma. As with cuboid fractures, the patient should be assessed carefully for the presence of Lisfranc’s injury. Treatment usually is by casting; however, displaced fractures require orthopedic assessment.

Dislocations of the Navicular, Cuboid, and Cuneiforms

Isolated dislocations of each of the midfoot bones have been described. These uncommon injuries often require open reduction. Emergent orthopedic consultation is required for these injuries.

Lisfranc (Tarsometatarsal) Fractures and Dislocations

Principles of Disease: Anatomy. Lisfranc injuries refer to any fracture, dislocation, or ligamentous injury at the tarsometatarsal joint (Lisfranc’s joint). This joint is composed of the articulations of the bases of the first three metatarsals with their respective cuneiforms and the fourth and fifth metatarsals with the cuboid. In concert, the tarsometatarsal joints act to allow supination and pronation of the forefoot. The intrinsic stability of Lisfranc’s joint is provided by the bony architecture and associated ligaments. The metatarsal bases form an arch, with the second metatarsal acting as the keystone. Lisfranc’s ligament itself joins the medial cuneiform with the base of the second metatarsal and provides crucial structural support. Strong transverse intermetatarsal ligaments join the bases of the second through fifth metatarsals. The joint is further supported by dorsal and plantar ligaments, plantar fascia, and insertions of the tibialis anterior and peroneus longus tendons at the first metatarsal base.

Pathophysiology. Lisfranc injuries carry a significant risk of long-term disability. They can be thought of as high-energy injuries, such as occurring in MVCs, or low-energy injuries, such as those occurring in sports activities. High-energy injury usually results in fractures or fracture-dislocations, whereas low-energy injuries can result in more subtle, isolated ligamentous injuries. Lisfranc injuries arise from three mechanisms—rotational forces, whereby the body twists around a fixed forefoot; axial loads, whereby the weight of the body drives the hindfoot into the bases of the metatarsals; and crush injuries. The most intuitive classification categorizes the direction of the dislocation in the horizontal plane (Fig. 51.18). In type A, or homolateral, injuries, all five metatarsals are displaced in the same direction. In type B, or isolated, injuries, one or more metatarsals are displaced away from the others. In type C, or divergent, injuries, the metatarsals are splayed outward in the medial and lateral directions. A component of dorsal displacement also is commonly present in displaced Lisfranc injuries, whereas plantar displacement is uncommon because of the joint’s bone architecture and strength of the plantar ligaments and fascia.

Low-energy Lisfranc injuries have been previously classified as stage 1 injuries, which are nondisplaced with low-grade strain, stage 2 injuries, in which a 2- to 5-mm diastasis exists between the first cuneiform and base of the second metatarsal, and stage 3 injuries, in which more than 5 mm of diastasis exists, and there is loss of metatarsal arch height. Because of ligamentous attachments, Lisfranc injuries are frequently associated with metatarsal fractures, usually of the second metatarsal base. Fractures of the cuboid, cuneiforms, and navicular also are common, occurring in more than one-third of cases. Lisfranc injuries may be complicated by vascular injury because a critical branch of the dorsalis pedis artery dives between the first and second metatarsals to form the plantar arch. Trauma to this vessel can cause significant hemorrhage and, uncommonly, vascular compromise.

Clinical Features. Most Lisfranc injuries are clinically obvious; however, findings may be subtle, and the true extent of the pathologic condition can easily be missed or misdiagnosed.
Seemingly trivial fractures, if viewed in isolation, may fail to reflect the serious soft tissue disruption that can be present. Some have estimated that the diagnosis is missed on initial ED presentation in up to 20% of cases.\textsuperscript{52} The clinical presentation varies with the extent of injury and displacement. Severe pain in the midfoot and inability to bear weight, particularly on the toes, are usual features. Paresthesias are occasionally present, and examination may reveal edema and ecchymosis. The dorsalis pedis pulse can be absent, or evidence of vascular compromise of the forefoot may be present. Typically, tenderness along the affected tarsometatarsal joints and pain with passive abduction and pronation of the forefoot are present, sometimes with pathologic mobility. It should be kept in mind that low-energy injuries may present with subtle findings, such as chronic pain and limitation in activity, with few other clinical signs.

**Diagnostic Testing: Radiology.** Standard radiographic views of the foot often are sufficient to diagnose injuries to the Lisfranc complex, although findings may be subtle (Fig. 51.19). The anteroposterior view allows assessment of the first and second metatarsals with their cuneiforms, whereas the oblique view assesses alignment of the third and fourth metatarsals with the lateral cuneiform and cuboid. The lateral foot radiograph allows assessment of metatarsal alignment with the cuneiforms in the sagittal plane. Typical radiographic findings are outlined in Box 51.3.

When Lisfranc injury is clinically suspected, and initial radiographs are normal, one should obtain additional imaging in the ED or in outpatient follow-up. CT scanning has been shown to detect Lisfranc injuries missed on plain film. In one study, using CT as a reference standard, plain films identified only 31 of 45 injuries.\textsuperscript{35} Despite diagnostic improvement, CT scanning does not image ligamentous structures and may miss low-energy or isolated ligamentous injuries which can still carry a burden of disability. MRI accurately images the Lisfranc joint and has been shown to predict instability, although studies have not proven its clinical value.\textsuperscript{9} Although often difficult to obtain because of pain, weight-bearing plain radiographs continue to have clinical value by demonstrating isolated ligamentous injury when plain radiographs fail to do so.\textsuperscript{55}

Initial assessment of the Lisfranc joint should include plain radiography. When plain radiographs are normal, and clinical suspicion of a Lisfranc injury is high, CT scanning is indicated. A further diagnostic option would be to obtain weight-bearing plain radiographs in the ED if pain can be adequately controlled. The American College of Radiology, in their guidelines on appropriate imaging, have suggested that CT scanning or MRI are appropriate

---

**Fig. 51.18.** Classification of Lisfranc injuries by direction of displacement of metatarsals with respect to the midfoot. Direction of displacement is indicated by arrows. The ligamentous anatomy of the Lisfranc complex also is depicted. (From Hardcastle PH, Reschauer R, Kutscha-Lissberg E, Schoffmann W: Injuries to the tarsometatarsal joint: incidence, classification and treatment. J Bone Joint Surg Br 64:349, 1982.)

---

**Box 51.3**

**Radiographic Findings Consistent With Lisfranc Injuries**

**ANTEROPosterior View**
- Loss of alignment of the medial border of the second metatarsal with the medial cuneiform
- Presence of a fleck sign from avulsion of the Lisfranc ligament
- Diastasis > 2 mm between base of the first and second metatarsals
- Compared to the uninjured foot; difference > 1 mm between base of the first and second metatarsals

**OBLIQUE View**
- Loss of alignment between the medial border of the fourth metatarsal and medial border of the cuboid

**LATERal View**
- Loss of alignment between the plantar aspect of the fifth metatarsal and the medial cuneiform
- Loss of dorsal alignment of tarsals with their respective metatarsals

Traumatic forefoot conditions are commonly underdiagnosed and often consist of more than one fracture or dislocation occurring simultaneously. As occurs elsewhere in the foot, forefoot trauma may lead to prolonged disability and dysfunction.

**Metatarsal Fractures**

**Principles: Pathophysiology.** Metatarsal shaft fractures arise from direct trauma (e.g., a crush injury from a heavy object) or indirect trauma (e.g., a twisting force applied to a fixed forefoot). Because of the nature of the mechanism of injury, associated phalangeal fractures often occur. Direct trauma may be highly disruptive, resulting in multiple metatarsal fractures and severe complications. The third metatarsal is the most commonly fractured, and metatarsal shaft stress fractures are common.

**Management.** Displaced or high-energy Lisfranc injuries are usually treated surgically, followed by non–weight-bearing casting for 12 weeks and wearing an orthotic for 1 year. Low-energy ligamentous injury without displacement can be treated with immobilization in a below-knee cast for 6 weeks.

**Disposition.** Any high energy or displaced Lisfranc injury requires emergency orthopedic consultation. Patients with a proven or suspected ligamentous Lisfranc injury should have orthopedic consultation in the ED or be immobilized in a below-knee cast or splint pending orthopedic follow-up as an outpatient.

The diagnosis of Lisfranc injury can be difficult, with subtle radiologic and clinical findings. Delayed treatment or misdiagnosis can result in significant complications and a poor functional outcome for which management is challenging. When radiographs in the ED are nondiagnostic, clinical suspicion of Lisfranc injury warrants further investigation and referral to an orthopedic surgeon for further assessment. This is particularly important for ligamentous injuries, in which the diagnosis is more challenging.

**Forefoot Injuries**

Traumatic forefoot conditions are commonly underdiagnosed and often consist of more than one fracture or dislocation occurring simultaneously. As occurs elsewhere in the foot, forefoot trauma may lead to prolonged disability and dysfunction.

**Metatarsal Fractures**

**Principles: Pathophysiology.** Metatarsal shaft fractures arise from direct trauma (e.g., a crush injury from a heavy object) or indirect trauma (e.g., a twisting force applied to a fixed forefoot). Because of the nature of the mechanism of injury, associated phalangeal fractures often occur. Direct trauma may be highly disruptive, resulting in multiple metatarsal fractures and severe complications. The third metatarsal is the most commonly fractured, and metatarsal shaft stress fractures are common.
Biomechanics is an important consideration in the approach to metatarsal shaft fractures. During stance, weight is distributed between the heel and forefoot, where it is spread across the metatarsals, with the first metatarsal carrying twice its share of the load. Great toe metatarsal fractures, although uncommon, require aggressive management because of their load-bearing function. Alignment of fractured metatarsals is important because dorsal or plantar displacement can lead to pain or functional disability by altering the transverse arch and load distribution. Dorsal angulation commonly occurs at the site of metatarsal fractures from the action of intrinsic muscles and toe flexors. This can contribute to metatarsalgia as a long-term consequence. Medial or lateral displacement, although less critical, can lead to the development of painful bony prominences or neuromas.

Clinical Features. Metatarsal shaft fractures cause weight-bearing difficulty and tenderness, which usually is maximal on the plantar surface. Axial compression of the involved toe is often painful, and ecchymosis usually appears within 12 hours of injury. Rotational alignment should be assessed by evaluating the position and plane of the involved digit.

Diagnostic Testing: Radiology. Standard radiographs are usually sufficient to diagnose metatarsal shaft fractures. Attention should be paid to displacement and angulation in the sagittal and mediolateral planes.

Management. Although local practice may vary, most undisplaced metatarsal shaft fractures of the second through fifth metatarsals are treated with a below-knee walking cast or boot for 2 to 4 weeks. Although not strictly necessary, pain may necessitate a period of nonweight-bearing.

The great toe metatarsal needs more aggressive management because of its biomechanical role and the stresses imposed on it during gait. Nondisplaced first metatarsal fractures should be treated with casting for 4 to 6 weeks. The patient should be nonweightbearing for at least the first 3 weeks, if not the entire period.

Reduction should be considered in any metatarsal shaft fracture with more than 3 mm of displacement or 10 degrees of angulation. Closed reduction, with toe traps and countertraction at the ankle, is often successful. Non-weight-bearing casting for 4 to 6 weeks should follow. The indications for open reduction are controversial but generally include the presence of compartment syndrome, unstable fractures, open fractures, fractures that have failed closed reduction, and multiple fractures. These are treated with fixation with Kirschner wires or plates. In particular, displaced first and fifth metatarsal shaft fractures are commonly treated operatively. Major forefoot trauma, with crushing and multiple open metatarsal fractures, necessitates an aggressive approach, with staged operative management.

Disposition. Although nonurgent orthopedic follow-up is reasonable, most nondisplaced metatarsal shaft fractures are suitable for management without orthopedic referral. More urgent orthopedic consultation should be obtained for patients with multiple or displaced fractures. Complications are rare in nondisplaced or minimally displaced metatarsal shaft fractures. Complex regional pain syndrome can occur and may be related to the unnecessary use of non-weight-bearing casting. Inadequate reduction, particularly in the sagittal plane, can lead to biomechanical problems and the formation of painful calllosities or metatarsalgia. Malunion in the mediolateral plane, particularly if involving the first or fifth metatarsal, can lead to the development of pressure points, neuromas, or biomechanical problems. Delayed union, nonunion, compartment syndrome, and soft tissue complications occur uncommonly.

Metatarsal Head and Neck Fractures. Metatarsal head and neck fractures, although similar in pathophysiology and assessment to shaft fractures, are commonly multiple and often result from direct trauma. Nondisplaced fractures may be treated with a walking cast for 4 to 6 weeks. These fractures, however, are frequently displaced, with the distal fragment pulled in a plantar and lateral direction by the flexor tendons. Precise realignment of neck and head fractures is important to maintain the transverse arch. Although reduction may be successful with toe traps, instability is common, and operative fixation is required more commonly than with shaft fractures. Displaced fractures require consultation with an orthopedist or urgent outpatient follow-up. Nondisplaced fractures can be followed by orthopedics, sports medicine, or primary care. Complications are similar to those seen with shaft fractures.

Metatarsal Base Fractures

Pathophysiology. Isolated fractures of the first through fourth metatarsal bases are uncommon. Most are nondisplaced transverse fractures within 1 cm of the tarsometatarsal articulation and arise as a result of direct trauma. An indirect mechanism may suggest an occult Lisfranc injury. The most commonly encountered metatarsal base fractures occur at the fifth metatarsal.

Fifth Metatarsal. Fractures of the base of the fifth metatarsal are commonly divided into three types according to anatomic location (Fig. 51.20). Zone 1 fractures are tuberosity avulsion fractures. Zone 2 fractures occur at the level of the fourth-fifth intermetatarsal articulation. Zone 3 fractures are proximal diaphyseal stress fractures. The term Jones fracture is commonly understood to describe zone 2 injuries.

Zone 1, or tuberosity fractures, are the more common and benign of the fifth metatarsal fractures. The tuberosity, which is easily palpated over the lateral edge of the foot, is fractured by a sudden inversion of a plantar-flexed foot. The mechanism of fracture is an avulsion by the lateral band of the plantar aponeurosis, although it is commonly thought to result from avulsion by the peroneus brevis.

Tuberosity fractures range from tiny flecks to lesions involving the entire tuberosity. They are usually extraarticular, although they may extend into the cubometatarsal joint. Often, these injuries masquerade as ankle sprains (see Box 51.2), making the fifth metatarsal base an important area to palpate in any twisting injury.

Zone 2, or Jones fractures, and zone 3 are more serious fractures, with a higher incidence of nonunion than in zone 1 fractures. Jones fractures occur at least 15 mm distal to the proximal end of the bone and involve the fourth and fifth intermetatarsal joint. Diaphyseal fractures result from a combination of forces generated when a load is applied to the lateral forefoot in the absence of inversion. Zone 3 injuries commonly are the result of stress fractures.

Clinical Features. The assessment of metatarsal base fractures is similar to that described for fractures of the metatarsal shaft. Pain often is diffuse and difficult to localize in these injuries, with the exception of the easily palpable fifth metatarsal tuberosity. Passive inversion also may be painful with a fifth metatarsal base fracture.

Diagnostic Testing: Radiology. Standard radiographic views easily demonstrate most metatarsal base fractures. Radiographs should be carefully assessed for fracture angulation, displacement, and articular extension. If the fracture is intraarticular, an estimation of the percentage of articular surface involved is essential for determining management. In difficult cases, CT may be helpful.

With fractures of the first through fourth metatarsal bases, it is important to recognize the potential for a Lisfranc injury. A fracture of the second metatarsal base is virtually pathognomonic for occult tarsometatarsal joint disruption. In assessment for a fifth metatarsal base fracture, differentiation between the tuberosity and diaphysis is important (Fig. 51.20). Standard ankle
All fifth metatarsal diaphyseal fractures (zones 2 and 3) should have outpatient orthopedic referral. Extraarticular and nondisplaced tuberosity (zone 1) fractures are suitable for primary care follow-up. Significant or displaced intraarticular, fifth metatarsal tuberosity fractures require orthopedic follow-up for consideration of operative repair.

Although fifth metatarsal fractures are seemingly minor injuries, approximately 30% of patients report pain, and 10% have persistent functional limitation at 1 year. Complications are rare in cases of fifth metatarsal tuberosity fractures, although fibrous nonunion of the fracture fragment can occur. Fifth metatarsal diaphyseal fractures are often complicated by delayed union, nonunion, or fracture recurrence because of poor healing subsequent to disruption of the metatarsal vascular supply. These complications occur in more than 50% of patients treated conservatively, often require aggressive surgical therapy, and have prolonged healing times.

Phalangeal Fractures

Pathophysiology. Phalangeal fractures are the most common forefoot fracture. The proximal phalanges are more commonly fractured than middle or distal phalanges. The proximal phalanx of the fifth toe is the most commonly injured. Fractures of the hallux often are displaced, whereas those of the lesser phalanges are often comminuted but are less commonly displaced.

Clinical Features. Although phalangeal fractures generally are considered minor injuries, they can lead to disabling sequelae. Patients present with acute pain and swelling of the affected toe, often with difficulty ambulating or wearing shoes. Examination may reveal tenderness, crepitus, and reduced range of motion. A subungual hematoma often is present if the distal phalanx is involved, and open fractures are common.

Diagnostic Testing: Radiology. As with metatarsal fractures, carefully assessed standard radiographic views are sufficient to demonstrate phalangeal fractures.

Management. Most phalangeal fractures are easily managed and heal well. Large and symptomatic subungual hematomas should be trephinated and, on rare occasions, nail bed repair may be required. Nondisplaced lesser phalangeal fractures should be stabilized by buddy taping, with placement of gauze between the splinted toes to prevent skin maceration. Phalangeal fractures often remain painful for 2 to 3 weeks until stabilized by callus. Use of a stiff shoe may be beneficial. If significant displacement or angulation is present, reduction should be performed with manual traction or toe traps after digital block anesthesia. Moderate persistent angulation or displacement is acceptable if the clinical appearance and function of the toe remain satisfactory. Rarely, operative fixation of lesser phalangeal fractures is indicated, particularly in cases with severe rotary deformity or open fractures requiring debridement.

Nondisplaced phalangeal fractures involving the hallux are treated by buddy taping, with a walking cast worn for 2 to 3 weeks if the toe is painful. Alternatives to standard casting techniques, such as the slipper cast, have also been described for phalangeal fractures. Displaced phalangeal fractures of the hallux require reduction. If the reduction is inadequate or unstable, operative fixation may be indicated. Unless completely nondisplaced, most intraarticular fractures involving the hallux are treated with operative fixation, although this has been controversial.

Disposition. In general, primary care follow-up is appropriate for phalangeal fractures. If displacement persists or causes cosmetic or functional concern, outpatient orthopedic referral is advised. Poorly reduced, or intraarticular hallux fractures should be splinted for urgent outpatient orthopedic follow-up. Complications of phalangeal fractures are uncommon. With intraarticular phalangeal fractures, particularly those involving the hallux, arthritis may be a late sequela. Symptomatic angular malunion and osseous deformity can occur with phalangeal fractures, and exostectomy is sometimes required.

Sesamoid Fractures

The sesamoids are two flat oval bones found in the tendon of the flexor hallucis brevis, under the head of the first metatarsal and, rarely, under the second to fifth metatarsal heads. Sesamoid fractures are uncommon, usually are caused by direct trauma or hyperextension of the great toe, and have been described in association with MTP joint dislocations. Stress fractures of the sesamoids also occur. A fracture should be differentiated from a bipartite sesamoid, which occurs in up to one-third of the population and also is more common on the medial aspect. Most sesamoid fractures heal without complication, with a below-knee walking cast for 3 to 4 weeks. Orthopedic consultation is suggested only for patients with nonunion or chronic pain.\(^{(655)}\) This can be arranged by the primary care physician.

Metatarsophalangeal Dislocations

Pathophysiology. MTP joint dislocations can occur in any joint and in any direction but are uncommon injuries because of the protection most footwear provides and inherent stability of the MTP and IP joints. First MTP joint dislocations require large forces and usually result from MVCs. These injuries, which are frequently open, are usually dorsal dislocations of the distal component caused by hyperextension of the MTP joint. Associated sesamoid fractures may be present. Complex dislocations, in which the sesamoids or local tendons prevent closed reduction, can occur. Second through fifth MTP dislocations usually are medial or lateral displacements that occur when the toe strikes or hooks an object. The most common is a lateral dislocation of the fifth MTP joint.

Clinical Features. First MTP joint dislocations usually are obvious because the toe is angled upward, with dorsal and proximal displacement of the proximal phalanx. Rarely, the sesamoids are palpable dorsal to the metatarsal, indicating a complex dislocation. Dislocations of the lesser toes may be more subtle in presentation, and comparison with the uninjured foot may be helpful. Neurovascular compromise is rare.

Diagnostic Testing: Radiology. Dislocations of the MTP joint are well-visualized on standard radiographic views of the foot. Radiographs should be scrutinized for signs suggestive of a complex dislocation, such as the sesamoids lying between the two articular surfaces or dorsal to the metatarsal head.

Management. Most MTP joint dislocations, particularly of the lesser toes, are easily reduced with longitudinal traction after appropriate analgesia or local anesthesia. Dorsal dislocations of the first MTP joint can be more challenging and may require initial accentuation of the deformity, in addition to longitudinal traction, for reduction. Joint stability should be assessed and repeat radiographs obtained after reduction of an MTP joint dislocation. After reduction, a walking cast with a toe plate is worn for 3 weeks, followed by physiotherapy to ensure adequate range of motion. Alternatively, buddy taping and an aluminum splint can be used for immobilization.

Disposition. Most MTP joint dislocations can be managed without orthopedic consultation. If crepitus or obvious instability is present, or postreduction radiographs show joint incongruity or an intraarticular fracture, orthopedic consultation should be obtained for possible fixation. First MTP joint dislocations that are open, show radiographic evidence of complexity, or do not easily reduce require emergent orthopedic consultation. Very rarely, MTP joint dislocations of the lesser toes require open reduction.

Complications are rare after MTP dislocation. Arthritis and reduced range of motion, particularly of the hallux, may occur. Dislocations for which the diagnosis is delayed for more than 3 weeks often are not amenable to closed reduction and may require metatarsal head excision.

Interphalangeal Joint Dislocations

IP joint dislocations are much less common than MTP joint dislocations and are sometimes overlooked. Most IP joint dislocations occur in the great toe and are a result of axial loading. IP joint dislocations usually involve dorsal displacement of the distal component. Reduction is performed with longitudinal traction after digital block anesthesia. Initial accentuation of the deformity may be necessary if reduction is unsuccessful with traction. If the dislocation involves the great toe, a walking cast with a toe plate for 3 weeks is indicated after reduction. Lesser toes require only buddy taping. As with the MTP joint, complex dislocations involving the first IP joint can occur, and orthopedic consultation in the ED for open reduction may be necessary. Very rarely, lesser toe IP joint dislocations are not reducible with closed methods and will require open reduction.

Foot Pain

Perspective. Foot pain, particularly in the absence of obvious trauma, poses a diagnostic and therapeutic challenge. Although a definitive diagnosis is often difficult to obtain in the ED, a structured approach, with a thorough history and physical examination, aids in management and disposition. Although consultation in the ED is rarely required, orthopedic or sports medicine follow-up on an outpatient basis is indicated for select cases.
The history should elicit prior injury, with attention paid to patterns of activity and overuse, as well as reviewing relevant medical history. Pain, which may occur on a spectrum from acute to chronic, is best approached anatomically by localizing symptoms to the hindfoot, midfoot, or forefoot.

**Hindfoot Pain.** Hindfoot pain is a common complaint that usually is the result of overuse rather than trauma.71 Bone pain in the hindfoot necessitates consideration of calcaneal or talar stress fractures. A calcaneal stress fracture may be suspected when pain is elicited on squeezing the calcaneus medially.

Most patients with hindfoot pain describe subcalcaneal heel pain, with plantar fascitis being the most common diagnosis. The differential diagnosis includes fat pad atrophy, acute rupture of the plantar fascia, lateral planar nerve compression, and tarsal tunnel syndrome.73

Plantar fascitis is a common and painful diagnosis in which patients may present to the ED having difficulty ambulating. The plantar fascia is a tough layer of the sole that is functionally significant during foot strike and the early stance phase of walking. Plantar fascitis is an overuse injury of insidious onset. Pain is classically felt on first weightbearing in the morning or after prolonged sitting. This progresses to persistent pain during activity. Tenderness is noted at the calcaneal insertion. The diagnosis of plantar fascitis is clinical, and primary care follow-up is sufficient. Although there are many options, the mainstays of management of plantar fascitis include activity and footwear modification, stretching, NSAIDs, and physiotherapy.

Plantar fascial rupture is a tear of the origin of the plantar fascia at the calcaneus. This injury usually occurs during the pushoff phase of gait. Swelling may be noted, and typically pain is elicited by passive dorsiflexion of the hallux. Treatment is nonsurgical, often with a period of cast immobilization for symptomatic relief.

Many tendons course through the hindfoot, particularly anteromedially, and tendinitis can occur (see Table 51.2). Other tendon pathologic conditions (eg, ruptures, dislocations, retinacular injuries) should be considered because they can result in significant functional disability.

**Midfoot Pain.** Isolated midfoot pain is less common than forefoot or hindfoot pain. Midfoot stress fractures, although uncommon, usually involve the navicular. A careful history and consideration of a low-energy ligamentous Lisfranc injury is important in patients with midfoot pain. Other causes of midfoot pain include symptomatic accessory bones, particularly the accessory navicular, os tibiale externum, and os peroneum.

**Forefoot Pain.** The forefoot is the site for a myriad of painful problems. Bunions, painful bursae, blisters, corns, calluses, hammer toes, and ingrown toenails all are diagnostically obvious but can pose therapeutic challenges. Many are the result of poor footwear or a biomechanical problem with the foot and respond to appropriate padding, avoidance of precipitants and, occasionally, surgical intervention.

**Metatarsalgia** is an often used, although loosely defined, term referring to pain in the region of the metatarsal heads.73 This is a common presenting complaint, with many potential causes relating to biomechanics of the forefoot. Metatarsal stress fractures should be considered in the differential diagnosis for any unexplained forefoot pain. Flexor or extensor tendinitis also can produce metatarsal area pain. Arthritis, sesamoiditis, or a sesamoid stress fracture should be considered when pain occurs in the plantar area of the hallux. The term turf toe refers to MTP joint inflammation of the hallux resulting from repeated hyperextension. It usually responds to symptomatic measures but can be a debilitating injury in some athletes.

An important cause of unilateral metatarsalgia is a perineural fibrosis of the intermetatarsal plantar digital nerve, more commonly known as Morton’s neuroma. This neuropathy usually involves the second-third or third-fourth intermetatarsal space, causing lancinating pain with weightbearing that can radiate to the toes and may be associated with paresthesias. Pain is reproduced when structures of the affected interspace are pinched or when the metatarsal heads are compressed together. Hence, pain may occur with tight-fitting footwear. Crepitus or a nodule may be palpable. Treatment ranges from footwear modification and physiotherapy to steroid injections and surgery for chronic and severe cases.74

Freiberg’s disease is an osteochondrosis of the metatarsal head, usually involving the second metatarsal, and is another cause of pain in this area. Ingrown toenails are a common affliction that can occur in any toe, usually the hallux. Often, the abnormality is perpetuated by short nail trimming, which affords the opportunity for a spicule of nail to grow under the nail fold. Allowing the nail to grow out and providing local care usually will lead to resolution, although chronic or recurring ingrowth necessitates partial or complete excision of the nail and germinial ablation. Antibiotics are indicated if infection is present.

**SPECIAL CONSIDERATIONS**

**Complex Regional Pain Syndrome**

Complex regional pain syndrome is a condition involving pain in the presence of trophic changes and vasomotor instability from inappropriate sympathetic nervous system activity; it was previously termed reflex sympathetic dystrophy.62,95 Complex regional pain syndrome occurs months after trauma, which may be major, as in a Lisfranc injury, or relatively innocuous. It produces pain of a diffuse burning, aching, or searing nature, together with evidence of vasomotor instability. Complex regional pain syndrome should always be considered in the differential diagnosis for chronic foot pain after trauma. Management is multifaceted, and usually is directed by a pain specialist.

**Stress Fractures**

**Pathophysiology**

Stress fractures can occur anywhere in the appendicular skeleton but are particularly common in the lower extremity. They are thought to occur as a result of extrinsic factors (eg, training volume, footwear, training surface) and intrinsic factors (eg, metabolic state, fitness, muscle endurance, anatomic alignment).96,97 The so-called female athlete triad of disordered eating, menstrual disturbances, and low bone mineral density is known to be associated with stress fractures.77

It is useful to categorize stress fractures as being high risk and low risk based on the rate of complications, including delayed union, nonunion, and persistent functional limitation. High-risk stress fractures often occur in bones with a vulnerable vascular supply. In the lower extremity, high-risk stress fractures include the femoral neck, anterior tibia, medial malleolus, navicular, proximal fifth metatarsal, and sesamoid bones.77

**Clinical Features**

Although the history is variable, most stress fractures produce localized pain of insidious onset, usually with aching over a period of weeks. Initially, symptoms occur after athletic activities, but later they limit such activities. Often, a predisposing factor, such as a training regimen change, is present. A menstrual history...
should be obtained in female patients because amenorrhea, often a result of overtraining, can predispose to stress fractures.

Physical examination may reveal swelling, point tenderness, or percussion tenderness. However, in most patients, these findings are absent, and the diagnosis is suspected by history alone.

**Diagnostic Testing: Radiology**

Initial plain radiographs are commonly normal because bone reaction in stress fractures depends on the length of time from symptom onset. Radiographic abnormalities in the metaphyses can take up to 4 weeks to develop, and those in the diaphyses can take 6 weeks. Although plain radiographs have low sensitivity for stress fractures, their specificity is high. The three important findings are periosteal new bone formation, endosteal thickening, and a radiolucent line.

Because only 50% of patients develop plain radiographic abnormalities, the diagnosis of a stress fracture can be easily missed. Traditionally, plain radionuclide bone scanning was the imaging modality of choice for stress fractures. Bone scans are nonspecific but extremely sensitive, usually showing abnormal uptake within 24 hours of injury. More advanced imaging techniques such as CT-SPECT and MRI have gained value in diagnosing stress fractures.78

**Management**

Athletic stress fractures are overuse injuries and necessitate an evaluation of training habits, equipment, and techniques. Most low-risk foot and ankle stress fractures resolve in 4 to 6 weeks with limitation of impact activities as guided by pain; most can remain weight-bearing and do not require immobilization unless symptoms are severe. High-risk stress fractures, including the anterior tibia, medial malleolus, navicular, base of fifth metatarsal, and sesamoids, require more aggressive management.

High-risk stress fractures of the foot and ankle should be treated with immobilization and nonweightbearing under the guidance of a sports medicine or orthopedic surgery specialist. High-risk stress fractures frequently are managed surgically, particularly those of the anterior tibia.

**Disposition**

Patients with confirmed low-risk stress fractures can be managed by primary care and can be weight-bearing as tolerated, with activity modification. If required by symptoms, these patients can be placed in a short walker boot for comfort. Patients with clinically suspected but unconfirmed stress fractures can be referred to sports medicine or orthopedic consultants to arrange further diagnostics, as indicated. All patients with high-risk stress fractures should be made nonweightbearing and immobilized, with arrangements made for outpatient orthopedic or sports medicine consultation.

**Tendon Injuries**

Acute tendon ruptures in the foot, apart from the Achilles and posterior tibial tendons, are rare. Although isolated ruptures of the flexor hallucis longus and anterior tibial tendons have been described, most tendon transections are the result of lacerations (see Table 51.2).

ORTHOPEDIC OR PLASTIC SURGERY CONSULTATION IS INDICATED FOR ANY TENDON TRANSECTION, BECAUSE APPARENTLY MINOR INJURIES CAN LEAD TO COMPLICATIONS, SUCH AS CLAW DEFORMITY. TENDON INJURIES ASSOCIATED WITH INNOCUOUS LACERATIONS ARE EASILY MISSED IF NOT CAREFULLY Sought. SPLINTING FOR 2 TO 6 WEEKS IS REQUIRED AFTER TENDON REPAIR.

**Crush Injuries, Amputations, and Major Vascular Injuries**

Rapid assessment, stabilization, and emergent consultation are priorities in the ED management of a major crush injury, amputation, or vascular injury of the foot. The injured limb is handled gently and can be irrigated with sterile saline solution to remove debris. The use of other irrigating solutions, exploration, or debridement, even if done carefully, is contraindicated. Antibiotics should be administered, as for any open fracture. The injured extremity can be dressed with well-padded, saline-soaked gauze, and the patient should receive appropriate analgesia. Compartment syndrome should be considered in all crush injuries.

**Compartment Syndrome**

**Principles of Disease: Pathophysiology**

Compartment syndrome is defined as an increase in pressure within a confined osseofascial space that impedes neurovascular function, resulting in tissue damage; it is discussed in detail in Chapter 42. By convention, four compartments—medial, central, lateral, and interosseous—are described in the foot, although as many as nine have been identified.78 Foot compartment syndrome is relatively rare, accounting only for an estimated 5% of limb compartment syndrome cases.79 As elsewhere, compartment syndrome in the foot constitutes a surgical emergency.

Pedal compartment syndrome is most commonly caused by high-energy injuries, such as crush injuries, Lisfranc fractures, calcaneus fractures, and midfoot or forefoot trauma. Pedal compartment syndrome after an ankle sprain has also been reported. Damage is related to the duration and magnitude of compartment pressure increase and the arteriovenous gradient. Compartment syndrome can develop anywhere from 2 hours to 6 days after an insult, although the peak incidence is at 15 to 30 hours.

**Clinical Features**

Compartment syndrome typically causes pain out of proportion to that expected for the injury. The pain is not decreased by immobilization and can be described as a feeling of tautness within the foot. Physical examination may reveal tense swelling and sensory deficits. Pain is exacerbated by any movement (active or passive) that stretches the muscles of the involved compartment. Peripheral pulses and capillary refill usually are initially normal in compartment syndrome and thus offer no reassurance when present. The presence of an open wound does not guarantee that all compartments are decompressed.

**Diagnostic Testing: Special Procedures**

Definitive diagnosis of compartment syndrome is by measurement of intracompartmental pressure. Pressure greater than 30 mm Hg is generally considered an indication for emergent decompression. Compartment syndrome can occur at lower pressures in hypotensive patients.78 More details on the pathophysiology, diagnosis, and treatment of this condition can be found in Chapter 42. Needle localization and distinguishing foot compartments is challenging. For this reason, and because of its importance in surgical decision making, measurement of pedal compartment pressures usually should be left to an orthopedic surgeon.
Management

Early identification and prevention of further tissue damage are important considerations in any patient with a mechanism consistent with the development of compartment syndrome. Circumferential bandages and casts should be avoided during early management. In diagnosed or suspected cases of compartment syndrome, the limb should be positioned at the level of the heart. Limb elevation beyond this point is contraindicated because it would decrease arterial flow, thereby narrowing the arteriovenous pressure gradient.

Disposition

If compartment syndrome is suspected, emergent orthopedic consultation is indicated for consideration of decompressive fasciotomy.

ACKNOWLEDGMENT

We gratefully acknowledge the contributions of Drs. Kendall Ho and Riyad Abu-Laban to previous editions of this chapter.

CHAPTER 51: QUESTIONS & ANSWERS

51.1. A middle-aged farmer presents after an accident with a plow with a crushed open distal tibia fracture. What is the appropriate antibiotic choice?

A. Cefazolin
B. Cefazolin and gentamycin
C. Cefazolin, gentamycin, and penicillin G
D. Ciprofloxacin
E. Pen VK and cephalaxin

Answer: C. Because the patient has a probable soil contaminant in his open fracture, he will need the addition of penicillin G to cover *Clostridium perfringens*. For low-energy injuries with mild to moderate contamination, a broad-spectrum cephalosporin is usually sufficient. Heavily contaminated wounds require the addition of gram-negative bacterial coverage, typically with an aminoglycoside. Adding penicillin G as a third antibiotic is necessary for farm- or soil-related crush injuries.

51.2. A 30-year-old woman complains of pain in the ankle and difficulty walking after attempting a jump shot while playing basketball. Her past medical history includes a recent urinary tract infection, for which she is taking ciprofloxacin. On physical examination, her ankle joint is not swollen, there is a palpable defect 4 cm proximal to the posterior ankle, and she has weakened plantar flexion. Which of the following is true concerning her condition?

A. Bohler’s angle should be less than 20 degrees.
B. In a seated position, squeezing the calf causes foot dorsiflexion.
C. It requires a stress radiograph view.
D. On the radiograph, there may be an opacification at Kager’s triangle.
E. Talofibular ligament laxity is present.

Answer: D. The patient has a ruptured Achilles tendon. On examination, a visible and palpable tendon defect 2 to 6 cm proximal to the calcaneal insertion may be present. In some cases of complete Achilles tendon rupture, weak plantar flexion may still be present because of the actions of the tibialis posterior, toe flexors, and peroneal muscles. When the Achilles tendon is intact, squeezing the calf muscles should cause passive plantar flexion of the foot (Thompson test). Later radiographs of the ankle may confirm rupture by showing opacification of the triangular fatty tissue–filled space anterior to the Achilles tendon (Kager’s triangle) or an irregular contour and thickening of the tendon.

51.3. A 24-year-old patient presents with pain in the left foot after a twisting injury. On physical examination, you find no point tenderness on the medial or lateral distal 6 cm of the malleoli, no proximal fibular tenderness, and no navicular tenderness. Which of the following physical findings would necessitate radiographs being taken in the emergency department?

A. Inability to ambulate to the car
B. Laxity on anterior drawer testing
C. Moderate swelling with ecchymosis
D. Tenderness at the base of the fifth metatarsal
E. Tenderness over the deltoid ligament

Answer: D. The Ottawa Ankle Rules advise ankle radiographs when any of the following are present: tenderness at the posterior edge of the distal 6 cm or tip of the lateral malleolus, tenderness at the posterior edge of the distal 6 cm or tip of the medial malleolus, or inability to bear weight for at least four steps immediately after the injury and at the time of evaluation. Foot radiographs in the setting of blunt ankle trauma are advised when any of the following are present: tenderness over the navicular, tenderness at the base of the fifth metatarsal, or inability to bear weight for at least four steps immediately after the injury and at the time of evaluation.

51.4. In what order are ligaments injured with inversion ankle injuries?

A. Anterior talofibular, calcaneofibular, and lateral talocalcaneal ligaments
B. Anterior talofibular, posterior talofibular, and tibiofibular syndesmotic ligaments
C. Calcaneofibular, tibiofibular syndesmotic, and deltoid ligaments
D. Posterior talofibular, anterior talofibular, and calcaneofibular ligaments
E. Posterior talofibular, calcaneofibular, and deltoid ligaments

Answer: A. Usually, the anterior talofibular ligament is injured first, followed by the calcaneofibular ligament if the deforming forces are sufficiently great. In addition, the lateral talocalcaneal ligament may be stressed with an inversion injury, leading to avulsion fractures at either of its attachment sites. Isolated calcaneofibular or posterior talofibular ligament injuries are rare.

51.5. A 20-year-old man presents complaining of foot pain after a motor vehicle collision. Radiographs show a fracture of the base of the second metatarsal. What is the most appropriate next step in the patient’s management?

A. Apply a hard-soled shoe.
B. Buddy tape second toe and arrange primary care follow-up.
C. Discharge on crutches with progressive weightbearing.
D. Obtain stress radiographs.
E. Splinting and orthopedic referral should be instituted if not the foot is improved in 2 weeks.

Answer: D. Findings suggestive of a Lisfranc injury include widening between the first and second or second and third metatarsal bases or any fracture around the Lisfranc joint. A fracture of the second metatarsal base is virtually pathognomonic of occult tarsometatarsal joint disruption. Significant Lisfranc injuries are usually treated with closed reduction and internal fixation with percutaneous Kirschner wires. This is followed by a non-weight-bearing cast for 12 weeks and an orthotic for 1 year. Treatment of a Lisfranc sprain usually involves immobilization for 6 weeks in a below-knee walking cast.
51.6. Pain on the medial aspect of the heel that is worse in the morning is suspicious for which of the following disorders?
   A. Compartment syndrome
   B. Foot sprain
   C. Osteoarthritis of the ankle
   D. Plantar fasciitis
   E. Septic arthritis

   **Answer:** D. Plantar fasciitis, an overuse injury of insidious onset, usually begins with pain on first weightbearing in the morning or after prolonged sitting. This progresses to persistent pain during gait. Pain and tenderness are localized to the medial aspect of the heel.

51.7. A 28-year-old man was working on a roof when he slipped and fell to the ground feet first. He presents with his right leg shortened and significant ankle swelling.

   Ankle radiographs show a comminuted distal tibial metaphysis fracture. Which of the following statements regarding this injury is false?
   A. Arthrodesis may be required.
   B. It has a high association with concomitant injuries.
   C. It has a low rate of complications.
   D. Orthopedic consultation for open reduction and internal fixation (ORIF) is necessary.
   E. Shear forces increase fracture comminution.

   **Answer:** C. The primary deforming force of a pilon fracture is one of axial compression, and the position of the foot at the time of injury determines the fracture location and pattern. Shear forces may cause increased comminution and fragment displacement with more extensive soft tissue injuries. Complications are common with pilon fractures, particularly in more severe injuries. Some patients with pilon fractures ultimately require arthrodesis.
Ch 52: Wound Management Principles

Barry C. Simon  |  H. Gene Hern, Jr.

**PRINCIPLES**

The goals of emergency wound treatment are to restore function, repair tissue integrity with strength and optimal cosmetic appearance, and minimize risk of infection. Risk of infection depends on the location, mechanism, host, and care. The risk for a clean facial wound produced by incision is less than 1%, whereas a dirty crush injury to the lower extremity may have more than a 20% risk. Wound infection generally results in delayed healing, decreased strength, and a poor cosmetic result. These facts highlight the need for high-quality wound care. Understanding the biology of wound healing and the technical aspects of wound treatment facilitates emergency management of these patients.

Emergency clinicians must also be aware of the medicolegal risk associated with soft tissue injuries. Including injuries to the hand, wound-related complaints are the fourth most common cause of malpractice claims against emergency clinicians. Missed foreign body, wound infection, and missed tendon or nerve injury are the most common complications leading to these claims.

**Anatomy of Skin and Fascia**

An understanding of skin anatomy leads to better appreciation of wound closure concepts and techniques. The skin is a complex organ that protects the body against bacterial invasion and ensures wound closure concepts and techniques. The skin is a complex organ that protects the body against bacterial invasion and ensures wound closure concepts and techniques. The skin is a complex organ that protects the body against bacterial invasion and ensures wound closure concepts and techniques. The skin is a complex organ that protects the body against bacterial invasion and ensures wound closure concepts and techniques. The skin is a complex organ that protects the body against bacterial invasion and ensures wound closure concepts and techniques. 

The skin and fascia vary in thickness from 1 to 4 mm, depending on the part of the body. The epidermis, the outermost layer, is several cell layers thick. The most important parts of the epidermis are the stratum germinativum (basal layer), where new cells originate, and the stratum corneum, the outermost cell layer that gives the skin its cosmetic appearance. The layer of skin directly beneath the epidermis is the dermis. The much thicker dermis is primarily composed of connective tissue. The dermis is the key layer for the ultimate healing of skin wounds. Optimal healing and minimal scar formation depend on the removal of debris and devitalized tissue from the dermis. The dermis also functions to anchor sutures placed percutaneously or subcutaneously.

The superficial fascia lies directly beneath the dermis and encloses the subcutaneous fat. This space must be irrigated and debrided to decrease the risk of infection. The deep fascia lies beneath the fat and is a strong, off-white sheath that covers and protects the underlying muscles and helps prevent superficial infection from spreading to deeper tissues. The deep fascia must be closed to maintain its protective and functional roles.

**Wound Biology**

Normal wound healing is a well-choreographed sequence of biologic events. It is described as an orderly process, but it actually represents multiple phenomena that occur simultaneously. These events include coagulation, inflammation, collagen metabolism, wound contraction, and epithelialization. Maintaining the balance of these events is crucial for normal healing. Delaying any of the stages may result in a weak closure and dehiscence. Prolonging segments of the process may affect the ultimate scar appearance.

Soon after tissue integrity is altered, the process of coagulation begins. Platelet release factors initiate and enhance a response from inflammatory cells. Capillary permeability increases to allow white blood cells to migrate into the wound. Neutrophils and monocytes act as scavengers to rid the wound of debris and bacteria. Monocytes transform into macrophages, which seem to have a major role in subsequent healing phenomena. In addition to providing wound defense, macrophages release chemotactic substances, signaling other monocytes to stimulate fibroblast replication and trigger neovascularization.

Collagen is the principal structural protein of most tissues of the body. Normal tissue repair depends on collagen synthesis, deposition, and cross-linking. Fibroblasts synthesize and deposit collagen compounds 48 hours after injury. Immature collagen is highly disorganized because it has a gel-like consistency.

After a series of enzymatic processes, characteristic fibrils are produced. Subsequent intermolecular cross-links are responsible for a major portion of the strength of the collagen fibril. The entire process depends on tissue lactate and ascorbic acid and is directly related to tissue arterial carbon dioxide partial pressure. In the absence of vitamin C, prolyl and lysyl hydroxylase do not activate, and oxygen is not transferred to proline or lysine. Underhydroxylated collagen is produced, and characteristic collagen fibers are unable to form. Wound healing is poor, and capillaries are fragile. Without oxygen to hydroxylate proline and lysine, a local condition resembling scurvy tends to occur.

Under normal conditions, collagen synthesis peaks by day 7, coincident with rapid increases in tensile strength. The healing wound has the greatest mass at 3 weeks but remodels itself during the next 6 to 12 months. However, the wound achieves less than 15% to 20% of its ultimate strength by 3 weeks and only 60% by 4 months.

Wound contraction is the movement of whole-thickness skin toward the center of the skin defect. Immediately after injury, the wound edges retract and increase the size of the defect. Normal skin tension along the lines of minimal tension produces this...
Uneven, jagged wounds have greater surface area than do linear lacerations. The skin tension is distributed over a greater area and is less per unit length of tissue. Meticulous reapproximation of the jagged edges results in a more appealing scar. Sharp débridement, converting a jagged wound to a linear laceration, is often unwise because it may cause too much tissue loss and produce a wider, more visible scar. Skin forces produced by muscular contraction and movements of flexion and extension influence healing and scar size. These dynamic forces are greatest where skin elasticity is necessary for function. Lacerations parallel to skin folds, lines of expression, and joints do not impair function or produce unattractive scars. Wounds that traverse the skin lines heal with conspicuous scars and may impair function. Knowledge of these lines and forces is necessary for optimal wound repair. In addition, the patient should be educated about wound healing and scarring potential.

**Biomechanical Properties of Skin**

Various forces (lines of tension) exist as a result of skin elasticity from collagen fibers. These static forces may vary more than fivefold with the respective area of body skin surface, but the static tension of a given area of skin remains constant. These static forces are shown clinically by the gaping of wounds after incision. The magnitude of static skin tension is directly related to ultimate scar width.

**History**

A detailed history should be obtained as part of routine wound evaluation. Serious complications can result when basic information is not obtained. If the patient has significant peripheral vascular disease, is immunocompromised, or has a high risk of a retained foreign body, wound care decisions may be changed. Essential historical information includes past medical history, mechanism and setting of injury, and tetanus status.
Risk Factors for Wound Infection

1. Location: Leg and thigh, then arms, then feet, then chest, then back, then face, then scalp
2. Contamination with devitalized tissue, foreign matter, saliva, or stool
3. Blunt ( crush) mechanism
4. Presence of subcutaneous suture
5. Type of repair: Risk greatest with sutures > staples > tape
6. Anesthesia with epinephrine
7. High-velocity missile injuries
8. Diabetes

Risk Factors

Risk factors for wound morbidity include prolonged time since injury; crush mechanism; deep wounds longer than 5 cm; age of the patient; high-velocity missiles; location on lower extremities; and contamination with saliva, feces, soil, or other foreign matter (Box 52.1). Three hours after acute trauma, bacteria proliferate to a level that may result in infection. Standard wound care guidelines for routine wound care recommend closure within 8 to 12 hours of injury yet new data suggests that timing is less important than the other risk factors.1 All risk factors must be considered to optimize wound care, and flexibility is required. Lacerations produced by fine cutting forces resist infection better than crush injuries. Reduction of blood flow to wound edges in the latter may increase the infective concentration of bacteria by a hundredfold. High-velocity missile injuries produce damage remote from the missile tract. The extent of injury may not be apparent for several days. Clean, finely cut lacerations on the face may be safely closed in some patients 24 or more hours after injury, whereas blunt lacerations to the leg or thigh may be treated with delayed primary closure as early as 4 to 6 hours after injury. For sutured wounds, location appears to have the strongest association with infection. Lacerations repaired on the leg and thigh may have an infection rate greater than 20%, those on the torso and other extremities greater than 10%, and those on the face and scalp less than 4%.

Optimal physical assessment of wounds requires patience, diligence, and an organized approach. Wound closure decisions are individualized for each laceration and each patient. In addition to the acute history, host specific data will influence management decisions: (1) immunocompetence of the host, (2) physical characteristics of the host (eg, peripheral vascular disease), and (3) structural defects that invite bacterial seeding (eg, damaged or prosthetic heart valves).

Physical Examination

Physical examination errors are minimized with optimal visualization and anesthesia. When the injury occurs on an extremity, use of a sphygmonanometer may help to ensure a bloodless field. The blood pressure cuff is placed proximal to the injury, and the extremity is elevated above the heart for at least 1 minute. Exsanguinating the extremity may be hastened by wrapping the limb tightly with an Ace bandage, beginning distally and ending at the base of the cuff. The sphygmonanometer is inflated to a pressure greater than the systolic pressure of the patient. Although this process causes the patient significant discomfort after 1 minute, the cuff can safely remain inflated for 2 hours. Alternatively, a peripheral nerve block or Bier block should be used if inflation longer than several minutes is contemplated.

DIAGNOSTIC TESTING

As noted earlier, attempts to visualize foreign matter by standard radiography are not as helpful as might be expected. The radiodensity of an object depends on the relative density of the matter and the adjacent tissue. Pieces of glass more than 1 mm thick are visible when appropriate views are ordered. Many organic substances, such as wood, are not visible on plain films, but specifically requested soft tissue views may increase the yield. A radiolucent shadow may be seen on close inspection, because the foreign substance displaces tissue in its path. Xerograms are better for identifying all foreign substances but is expensive and results in exposure to radiation. Ultrasonography is a good technique, but the small size of many foreign bodies and pockets of air, edema, pus, and some calcifications may produce confusing echoes, limiting its clinical usefulness. When simpler, standard methods fail to locate a foreign body that is likely or definitely present, we recommend that ultrasonography or a CT scan should be considered.

MANAGEMENT

Anesthesia

After an appropriate neurovascular examination is documented, the involved tissue should be anesthetized. Careful physical examination and thorough cleansing, irrigation, and débridement require that the patient be free of pain. Regional anesthesia may be preferable for wounds innervated by one superficial nerve. Injections at the wound site produce swelling and further distortion of landmarks. With a regional block, more than one laceration may be repaired in the same nerve distribution without
Anesthetic Agents

Lidocaine (Xylocaine) is the most common agent used for local and regional anesthesia. It is safe and fast acting. Onset of action for direct infiltration occurs within seconds, and the effects last 20 to 60 minutes. When lidocaine is administered as a regional nerve block, onset occurs in 4 to 6 minutes and the effects generally last 75 minutes, although the block may remain effective for 120 minutes. A 1% lidocaine solution contains 10 mg/mL. It is safe to use 3 to 5 mg/kg, not exceeding 300 mg at a single injection. More volume can be added safely every 30 minutes. When epinephrine is added, the resulting vasoconstriction prolongs the effect for 2 to 6 hours, and the safe dose is increased to 5 to 7 mg/kg. However, the addition of epinephrine has been shown to delay healing and lower resistance to infection. Lidocaine with epinephrine should be avoided in wounds with higher risks of infection and when tissue viability is of concern. Traditional teaching has been to avoid epinephrine in the fingers and toes because of the risk of vasoconstriction in small arterioles. However, recent literature suggests that with careful screening, epinephrine can be safely used in digital blocks. Digital artery vasospasm, accidentally induced by local injection of epinephrine, can be reversed successfully with a local injection of 0.5 to 2 mg of subcutaneous phentolamine or application of topical nitroglycerin.

Bupivacaine (Marcaine) provides anesthesia that is equal to that of lidocaine. Onset of action is slightly slower than that of lidocaine, but the duration of anesthesia is four to eight times longer. These benefits suggest that bupivacaine is the preferred local anesthetic agent for the care of most wounds. In adults, the maximal reported safe dose is approximately 2.5 mg/kg without epinephrine and 3.5 mg/kg with epinephrine. The dose can be repeated every 3 hours, not exceeding a total of more than 400 mg in a 24-hour period. The maximal intraoral dose is 90 mg.

Local injection of lidocaine should be done with a 27-gauge needle; the slower the injection, the less pain produced. The rate of injection through a 30-gauge needle is far too slow, and the thin needle is difficult to control. A 25-gauge needle is acceptable, but the more rapid injection can result in greater patient discomfort. The needle should be introduced through the cut margin to minimize the pain of the injection. Concerns of spreading bacteria into the adjacent uninvolved tissue and increasing the frequency and severity of wound infections are unfounded. The pain of injecting lidocaine can be ameliorated with the addition of bicarbonate to buffer the solution. The shelf life of the lidocaine-bicarbonate mixture decreases, but it remains effective for 1 week at room temperature and for 2 weeks if refrigerated. Adding sodium bicarbonate in a 1:10 volume ratio to lidocaine (1 mL bicarbonate and 10 mL lidocaine) decreases the pain of injection without compromising the quality of anesthesia. A much smaller dose of bicarbonate is added to bupivacaine because the alkalization results in precipitation. A 1:100 volume ratio (0.1 mL of bicarbonate and 10 mL of bupivacaine) has been found to be effective. Warming the anesthetic solution is also an effective means of decreasing the pain of injection.

Topical anesthesia may be an effective painless alternative. Studies show that a combination of lidocaine (4%), epinephrine (0.1%), and tetracaine (0.5%) (LET) can function effectively on skin lacerations, especially on the face and scalp. Administration by soaking a cotton ball with 3 mL of the combined solution and applying it to the wound for 20 minutes. A gel formulation is available and may be preferred, because it’s easier to control and to limit run off and inadvertent contact with mucous membranes. The duration of action is 45 to 60 minutes following the removal of the gel from the wound. Toxicity is rare when the dose administered is no more than 3 cc and mucous membranes are avoided. Potential toxic effects of lidocaine and tetracaine are related to the cardiovascular and central nervous systems. Cardiovascular effects may include arrhythmia, ectopy, decreased contractility, and cardiac arrest. Central nervous system toxicity may include headache, irritability, restlessness, blurred vision, and seizures. With use of a topical anesthetic, time to repair is reduced, patient acceptance improves, and landmarks are left undisturbed.

Although LET has been found to be very safe, weight-based dosing has been recommended for children weighing less than 17 kg. Administering a maximum of 0.175 mL/kg of LET will prevent the application of more than 5 mg/kg of lidocaine. No cases of methemoglobinemia have been reported, but given the small risk associated with tetracaine extra caution is advised in neonates.

Tetracaine, adrenaline (epinephrine), and cocaine (TAC) was the original topical anesthetic solution. This combination is as effective as LET on the face and scalp and more effective elsewhere on the body. However, the risk of complications is greater, and the complexities tied to the handling of cocaine limits its utility.

Eutectic mixture of local anesthetics (EMLA) is a cream used to produce anesthesia of wounds and intact skin. The active ingredients are lidocaine (2.5%) and prilocaine (2.5%). The micron-sized particles of the cream are designed to penetrate layers of the skin to lessen the pain of needle penetration. Studies have demonstrated efficacy in venipuncture, immunization administration, lumbar puncture, and laceration repair. Peak effect requires about 1 hour and continues for 30 to 60 minutes after removal of the cream.

Allergy

Allergy to local anesthetics is uncommon. Two distinct groups of “caine” anesthetics exist. The esters include procaine, tetracaine, and benzocaine. The second group, including lidocaine and bupivacaine, belong to the amide family. Allergy to the esters is uncommon. True allergy to agents in the amide family is rare.

The subject of allergy is complicated further, because multidose vials contain the preservative methylparaben, an ester related structurally to anesthetics in the ester family. Apparent allergic reaction to lidocaine or bupivacaine may be a reaction to the methylparaben. Single dose, preservative free, vials of lidocaine and bupivacaine should be standard stock in every emergency department (ED).

When allergy to a local anesthetic is known or strongly suspected, alternatives are available. No cross-reactivity occurs between the amide and ester families, so an agent from a different group may be chosen. A test dose of 0.1 mL may be administered intradermally before proceeding. The patient should be observed for 30 minutes, and as with any allergy testing, the emergency clinician should be prepared to treat all complications. Aqueous diphenhydramine (1%) has also been shown to provide effective local anesthesia.

Skin Preparation

Disinfection of the skin (not the wound itself) may be accomplished with several different agents. The ideal agent is fast acting, has a broad spectrum of antimicrobial activity, and has a long shelf life. Povidone-iodine (Betadine) and chlorhexidine (Hibiclens) have all three characteristics. Although excellent as skin disinfectants, both products are toxic to wound defenses and may increase the incidence of wound infection. Povidone-iodine is effective against gram-positive and gram-negative bacteria, fungi,
and viruses. Chlorhexidine is less effective against gram-negative bacteria, and its efficacy against viruses is unknown. Care must be taken to avoid spilling these substances into the wound. Exposure of the eye to these agents can be detrimental. Chlorhexidine has been shown experimentally and in case reports to produce serious permanent corneal opacification. Current data suggests that chlorhexidine-alcohol preparations are safe and more effective at limiting infection compared with povidone-iodine solutions.5,6

Body, facial, and head hair is usually removed to clean and examine the wound, although this is not necessary to diminish the risk of wound infection. Removal of the hair makes it easier for the patient to keep the area clean and ultimately facilitates accurate suture placement and removal. Exceptions are parts of the body where hairlines provide important landmarks for the accurate reapproximation of tissue margins, most notably the eyebrow. Reports of inconsistent or absent eyebrow hair regrowth suggest that eyebrow hair should not be shaved.

Surgical studies show that hair removal with a razor is three to nine times more likely to result in a wound infection than clipping the hair. It seems that the razor damages the infundibulum of the hair follicle. The wounded follicle provides access for bacterial invasion and ultimately infection. For wounds considered to be at high risk of infection, clipping may be done with electronic shears or scissors. Another option is to apply a petroleum-based product to the hair adjacent to the wound margins, allowing the provider to keep the hair away from the surgical field.

**Wound Preparation**

**Débridement**

Débridement is the removal of foreign matter and devitalized tissue from the wound. With respect to ultimate wound healing and risk of infection, débridement is the most important consideration in wound care. The presence of any devitalized tissue in the wound delays healing and significantly increases the risk of infection. However, the benefits of débridement have to be weighed against the consequences of producing a larger tissue defect. The resultant closure is exposed to higher tension and may result in a wider scar. Skin edges that are clearly devitalized are debrided before wound closure. On the trunk, where there is little concern for specialized tissue, wide excision and débridement are feasible. On the face and hands, where all tissue must be saved if necessary, excision is no longer an option. On the face and hands, wide excision and débridement are used. On the hands, débridement is the preferred method of wound preparation because it is nontoxic to the tissue and does not reduce tissue integrity and may increase the infection rate. A 1% solution is toxic to polymorphonuclear neutrophil leukocyte activity and may increase the infection rate. A 1% solution is safe and effective with little or no toxicity. Detergent-containing cleaners, such as povidone-iodine scrub, may be excellent for skin preparation but are toxic to tissue defenses and should never be allowed to contaminate open wounds.

Although many different irrigation solutions may be beneficial, it seems that the key to cleansing is high-pressure irrigation rather than the type of solution used. Tap water irrigation soon may become the preferred method of irrigation, because it is safe, is effective, requires no preparation, and is less expensive.

**Irrigation**

The quality of mechanical cleansing is one of the most important determinants of wound prognosis. The most effective form of wound cleansing is high-pressure irrigation. Irrigating with pressures greater than 7 pounds per square inch (psi) significantly decreases the number of bacteria and the incidence of infection. Although several commercial devices are available, attaching an 18-gauge needle to a 35-ml syringe yields a force of 7 to 8 psi. High pressures of 50 to 70 psi may be obtained with a commercial water pick. These pressures may cause some tissue damage, but the beneficial effect of ridding the wound of bacteria and debris outweighs this risk. Simply soaking the wound in an antiseptic solution is not beneficial and may be harmful. Scrubbing the wound with a sponge with large-pore cells inflicts tissue trauma and impairs the ability to resist infection. Tissue damage can be decreased by use of a sponge with a fine size of pore cell. Adding a surfactant further minimizes the mechanical trauma inflicted by the sponge. Flooding the wound under low pressure via a bulb syringe or gravity alone does not reduce the incidence of infection, regardless of the agent used.

At least one study has shown little benefit to any irrigation in facial and scalp lacerations. This study prospectively compared outcomes of almost 2000 immunocompetent patients. Infection rates and cosmetic outcomes were similar in the irrigation and the non-irrigation groups. We recommend irrigation only for scalp wounds more than 5 cm long and those with other high risk features.

**Wound Closure**

**Decision-Making**

The first determination required is whether the wound should be treated open or closed. Each wound, patient, and clinical circumstance must be handled individually. As discussed in the Risk Factors section, most wounds have a low risk of infection and can safely be closed primarily. A small study from Europe failed to show a difference in infection risk for wounds sutured more than 6 hours after injury.7 At the other end of the spectrum, some wounds must never be closed at the time of their initial ED visit. A large stellate laceration to the foot produced by blunt force and contaminated with dirt and grease must be cleaned and left open to be closed later. Human and animal bites to the hand are additional examples of wound that should not be closed primarily. Physician judgment is often the best method for deciding when it is safe to close a wound. In one study in which hand wounds were
described as dirty, 22% became infected. When the injury was documented to be clean, the incidence of infection was 7.1%.

Three wound closure options are available. The wound may be (1) closed primarily in traditional fashion, (2) closed in 4 or 5 days (delayed primary closure), or (3) left open and allowed to heal on its own. Delayed primary closure is a safe alternative to traditional primary closure. Overall healing time is not affected, and the risk of infection is greatly decreased if proper technique is used. When a wound is slated for delayed primary closure, it is prepared, debrided, and irrigated in the same manner as for immediate closure. The wound should be packed to prevent it from closing on its own. If the wound is on an extremity, the injury should be splinted and dressed, and appropriate wound care instructions should be given. The patient should return for a wound check and packing change in 24 hours and should be instructed to follow up in another 72 hours for definitive repair, with wound closure undertaken 96 to 120 hours after injury. No studies offer guidelines for prophylactic antibiotic use when delayed primary closure is the treatment option. Extrapolation from other wound studies strongly suggests that antibiotics offer no benefit.

Individuals who do not seek medical care after an injury select the option of leaving a wound open to heal on its own. Most patients who visit an ED with a laceration undergo some form of wound closure. Yet one study that examined unsutured hand lacerations less than 2 cm long followed patients for 3 months and found that there was no significant difference in cosmetic appearance, and there was no difference in time to resumption of activities of daily living.

Closely approximating wound edges is occasionally discussed as an option in the treatment of contaminated wounds. This choice should rarely be considered. The loosely closed wound approximates the tissue margins enough to allow the wound to seal itself completely within 48 hours. The infection risk when this method is used is the same as when the wound is closed traditionally.

Wound Tension

The goal of wound closure is optimal anatomic and functional reapproximation of tissue with minimal risk of complication. Consideration must be given to the wound’s size, shape, location, depth, and degree of tension. Wounds with high static and dynamic tension that require meticulous closure cannot be closed with tape or staples. Delicate approximation of wound edges under tension can be accomplished only with suture.

Several techniques may be used to reduce wound tension. Deep sutures may be placed in subcutaneous tissue to help bring the wound margins closer together. In this manner, forces on the skin are reduced, and potential dead space can be closed. Care should be taken to avoid suturing adipose tissue, because it may become necrotic, increasing the likelihood of infection. The number of dermal sutures depends on the characteristics of the wound. In general, the number should be kept to a minimum, because suture material acts as foreign matter in the wound and can increase the risk of infection. Subcutaneous sutures should never be placed in the hand or foot because of the major structures that reside near the surface. Another method of ameliorating static tension from cut edges of the wound is to undermine at the lacerated margin. Undermining helps free the dermis from its deeper attachments, allowing the skin edges to be approximated with less force. Care must be taken to preserve the blood supply to the wound margins and not increase dead space in the process.

Suture Technique

Careful surgical technique is important to optimize the ultimate repair. If possible, pickups, hemostats, or forceps should not be used, especially on wound margins. Blind clamping in a wound can damage a nerve, artery, or tendon. Wound margins should be everted and the sutures tied just tightly enough to allow the edges to approximate lightly. The edges can be everted by ensuring that the needle enters and exits perpendicular to the skin. Wounds with opposing margins of different thickness can be difficult to close. If this difference is not considered and corrected, the ultimate scar has uneven margins that cast a shadow on the skin and is unsightly. In closing these wounds, the needle should be pulled through the cut margin of one side before entering the opposite edge. This method gives the emergency clinician the best opportunity to take an equivalent amount of tissue on both sides of the wound. Viable edges of a jagged wound must be meticulously reapproximated. Because of the greater surface area and the ultimate contraction of the wound, preserving the jagged edges results in a more “natural” scar.

Most lacerations are closed with running or interrupted percutaneous suture. The running technique is appropriate for linear lacerations under minimal tension when there is a low risk of infection. This technique is more rapid, requires less suture material, and yields equivalent cosmetic results. Curvilinear or jagged wounds are best closed with interrupted sutures to distribute tension properly. Because tensile strength of interrupted sutures may be superior, wound edges subjected to higher levels of tension should be closed with interrupted sutures.

Basic and Advanced Techniques

Simple Sutures. Wound closure with simple interrupted sutures is the most common method of laceration repair in the ED. The placement of simple sutures yields excellent cosmesis and a low infection rate.

Procedure. The needle is placed to one side of the laceration margin and enters the skin at approximately 90 degrees. To pass the needle through the tissue, the clinician supinates his or her wrist and guides the needle deep but parallel to the skin surface. Wrist supination is extended as the needle exits the skin on the opposite side perpendicular to the surface. Proper technique produces wound edges that are slightly everted and are lightly touching. The art of the process takes into consideration swelling while being careful not to secure the suture too tightly, because necrosis of the wound margin tissue can seriously compromise healing.

Intradermal (Buried) Sutures. Placing cutaneous sutures in wounds under tension can lead to ischemia of the wound margin and an unsightly scar. Proper placement of buried intradermal sutures helps to approximate dermal margins and reduce wound edge tension. Buried sutures should not be used in contaminated wounds, because they increase the risk of wound infection. Sutures through adipose tissue also increase infection and do not relieve skin tension.

Procedure. Placement of buried sutures differs from traditional suturing because of the need to bury the knot deep to the skin. Failure to do this can interfere with dermal healing and can leave a small lump under the surface of the skin. The needle is introduced deep in the wound in the subcutaneous tissue and emerges from the dermis below the skin surface. The needle is reintroduced in the dermis on the opposite wound margin and emerges from the subcutaneous tissue at the same level on the opposite side. The knot is secured and remains buried deep below the skin surface.

Scalp Laceration Repair. In contrast to small lacerations elsewhere on the body, most scalp lacerations require repair because of the propensity to bleed profusely. The dense connective tissue beneath the skin tends to hold vessels open and delay hemostasis. Frontal scalp lacerations in young men should be considered to be a cosmetically significant wound. Although the scalp
laceration currently may be well hidden by hair, most men experience some balding. Care must be taken to explore the laceration thoroughly to look for a defect in the galea, an injury that requires repair with deep sutures. Staples may be ideal for the skin closure of simple linear scalp lacerations. Hair is less of a problem in placing staples, staples can be placed more quickly than traditional suture, and staples are easier to see and can be removed 1 to 3 days earlier than traditional sutures (Fig. 52.3). Staples may produce artifact on CT scans, but useful information may still be obtained if CT is necessary. Staples may move during magnetic resonance imaging (MRI) and should not be placed if this imaging modality is being considered. Lightweight stapling devices are available. Most devices come preloaded with five or more staples and are easy to use. Hair apposition may also be an option for the closure of many scalp wounds. The technique involves grabbing a bundle of hair on both sides of the wound and then twisting the hair bundles with a hemostat. A small dab of cyanoacrylate glue is applied to the twisted hair to prevent unraveling. Patient satisfaction is high with this approach.10

Traditional sutures are used to repair most scalp lacerations, usually with standard nylon suture. Absorbable chromic gut can be used in children and in adults who may not return for suture removal.

**Procedure.** Anesthesia with epinephrine is recommended to help control bleeding. Hair removal is necessary only if the hair makes closure difficult. A defect in the galea is closed with 3-0 or 4-0 absorbable suture. Failure to repair the galea can lead to a cosmetic deformity related to frontalis muscle function. Linear superficial scalp lacerations that do not require deep sutures can be closed with staples or with monofilament nylon sutures applied with a simple interrupted or running technique. Jagged or macerated lacerations may require some débridement and horizontal mattress sutures. When one chooses to staple a scalp laceration, the adjacent skin margins are pinched together with forceps to evert wound margins. The “mouth” of the stapler is placed gently on the skin surface, taking care not to indent the skin. The handle of the stapler is squeezed carefully to eject the staple into the tissue. Ideally, the staple closely approximates the wound margins without indenting the surface of the skin. For release of the staple, the wrist is pulled back to disengage itself from the last staple.

Vigorously bleeding scalp lacerations often need temporizing measures to control bleeding while the patient is being evaluated and resuscitated. An anesthetic agent with epinephrine should be used and may be helpful to control some bleeding. Blindly clamping in an attempt to control bleeding is unwise and not likely to be successful. Raney scalp clips can be rapidly applied to the wound margins to quickly gain control of the bleeding. An applicator is used to apply and remove the clips so that they can be replaced with sutures once the patient has been stabilized. The clips are plastic and will not interfere with CT or MRI.

Staple removal is simple, especially if the patient has kept the wound clean and free of dried secretions. The dual prongs on the
as, over joint surfaces), may need assistance to ensure eversion of the wound margins. Vertical mattress sutures may be ideal to accomplish both tasks.

Procedure. A vertical mattress suture is a combination of deep and superficial components. The needle is introduced at a 90-degree angle approximately 1 cm from the wound margin. The needle courses through the depth of the wound and emerges on the opposite side, 1 cm from the laceration margin at a 90-degree angle. The needle is reintroduced 1 or 2 mm from the epidermal edge for final approximation of the wound.

Horizontal Mattress Sutures. Horizontal mattress sutures are useful to help disperse excess skin tension and to evert wound edges. The scalp, which has minimal skin mobility, is one area where gaping lacerations may benefit from this tension-reduction method. Horizontal mattress sutures may also be beneficial in thin, fragile skin of elderly people and for lacerations that have lost tissue from the injury or débridement.

Procedure. The initial step is to pass the needle as for a simple interrupted stitch (Fig. 52.4). On exiting the skin, however, the needle is reintroduced approximately 0.5 cm adjacent to the exit point. This second “bite” reemerges 0.5 cm adjacent to the initial insertion point and is tied. Unlike with vertical mattress sutures, each bite is always the same distance from the wound margin.

Dog-Ear Deformity Repair. Some redundant tissue may result on one side of the repair as the closure nears completion,
especially in the closure of curvilinear lacerations. This redundant tissue generally can be avoided by placing the initial suture in the middle of a curvilinear wound. If the clinician has limited experience, excision and undermining of tissue are likely to result in complications and should not be attempted.

**Procedure.** The laceration repair begins in a traditional manner and continues to approximately the final 1 cm of the wound (Fig. 52.5). A short incision (approximately 1 cm) is made from the end of the laceration at a 45-degree angle. The angle is cut toward the side of the redundant, bunched tissue. In most cases, the subcutaneous tissue from the start of the dog-ear defect to the newly created end of the wound must be gently undermined to mobilize the skin. The next step, the final step before suturing, is the most important. The work that has just been completed leaves a small triangular piece of excess tissue. The redundant piece is gently lifted with the tissue forceps and excised in a line parallel to the incision made above. The wound can now be closed with simple interrupted suture technique.

**Corner Stitch (Half-Buried Horizontal Mattress Sutures).** Jagged and triangular wounds create corners that can be difficult to repair. The clinician must avoid placing the suture directly in the tip of the flap. This practice may “stretch” the tissue and further compromise blood flow to the wound margin. The corner stitch allows optimal tissue approximation with minimal tension.

**Procedure.** The needle is introduced percutaneously through the non-flap side of the wound a few millimeters from the corner of the wound (Fig. 52.6). The angle is cut toward the side of the redundant, bunched tissue. The needle is passed horizontally through the dermis of the flap. The final step is to pass the needle into the dermis of the non-flap aspect of the wound a few millimeters from the opposite side of the corner. The suture is led out

Suture. The ideal suture is inert to metabolism, is resistant to infection, has great tensile strength, does not tear tissue, is easy to work with and tie, and is available in convenient colors with a variety of cutting and noncutting needles. A common classification of suture material relies on relative absorbability. In general, the materials that maintain their tensile strength for more than 60 days after implantation have been defined as nonabsorbable. Materials that undergo rapid degradation in tissue and lose their strength in less than 60 days are considered absorbable. A second classification considers the source and nature of the material. Biologic substances, which include catgut, collagen, silk, linen, and cotton, generally produce the greatest tissue reaction and have the lowest relative tensile strength but have good knot security. These characteristics are in contrast to synthetic materials, such as polyester (Dacron), polyamide (nylon), polypropylene (Prolene), polyglycolide and polylactide polymers (Dexon and Vicryl), polydioxanone (PDS), and steel, which usually have less tissue reactivity, greater strength, and less knot security.

Knotting properties and handling characteristics tend to vary inversely. Knot security is of particular importance in maintaining wound closure and the patient’s confidence in the physician. Sutures with smooth or slippery surfaces produce little friction and glide effortlessly through tissue and are easy to tie. Smoother

Materials

In the Middle Ages and earlier, materials used to close wounds included flax, hemp, fascia, hair, linen strips, pigs' bristles, reeds, grasses, and even the mouth parts of the pincher ant. In the early 1900s, natural organic protein products, including silk, cotton, and catgut, were the only available substances. Polyester (Dacron) and nylon were the first synthetic materials, available in the 1940s. Since then, a host of other synthetic materials have become available.

V-Y Wound Closure. The V-Y closure is indicated for the repair of V-shaped wounds with tissue loss or with nonviable margins that must be trimmed. The tissue loss is such that the adjacent mobile tissue is not sufficient to close the remaining defect.

Procedure. Nonviable tissue is trimmed with fine iris scissors (Fig. 52.7). The long V-shaped portion of the wound is sutured with simple interrupted percutaneous stitches. This first step brings the tip of the flap closer to the newly created corner of the wound. A corner stitch is used to secure the tip of the flap. The remaining limbs of the Y can be repaired with simple interrupted stitches. Some degree of undermining is likely to be needed to mobilize tissue to close the defect. Débridement of too much tissue can make the final repair more difficult and can distort adjacent anatomy.

common sutures used on skin, produce little tissue reaction and offer good tensile strength. They tend to be stiff, produce discomfort near the lips, have poor knot security, and may be difficult to work with. A braided, coated polyester nonabsorbable material, such as Ethibond, is easier to work with and has better knot stability. Although Ethibond is more expensive than nylon, its characteristics and added patient comfort suggest that it may be preferable. Absorbable suture materials, such as polyglycolide and polylactide polymers (Dexon and Vicryl), have been used strictly for subcutaneous and mucosal closures. Their highly reactive nature allows them to be broken down and absorbed over weeks. Chronic catgut, another absorbable material, has been shown to be safe and effective for the closure of scalp wounds in children.

**Needles.** Surgical needles are available in a variety of sizes and shapes with myriad other characteristics. Cutting needles may be reverse cutting, conventional cutting, taper cut, or precision point. Most emergency wounds may be closed with a conventional cutting needle. In addition to its sharp point, it has two opposing cutting edges, with a third on the inside curve. Precision point needles are similarly shaped but are honed 24 extra times and maintain their added sharpness longer. These needles are used for delicate plastic or cosmetic surgery. Noncutting needles are reserved for organ repair and subcutaneous suturing. Cutting needles may also be used to repair subcutaneous tissue. Needle nomenclature is confusing and varies by manufacturer.

**Tape.** Tape closure may be superior to closure with sutures and staples if applied in the appropriate circumstances. In general, the laceration should be linear and subjected to weak static and dynamic forces. Tape is not considered for wounds requiring meticulous tissue approximation. Compared with other closure materials, tape is associated with lower risk of infection, less expense, and less physician time. In addition, a painful injection of local anesthetic is not needed.

The ideal wound closure tape allows water and gas exchange and possesses elasticity, strength, and optimal adhesiveness. For adhesive properties to be maximized, tincture of benzoin should be painted on the skin adjacent to the wound. Care must be taken to avoid introducing benzoin compound in the wound. A nonwoven, microporous tape, which is not reinforced, has been found to best meet these requirements.

**Staples.** Staples offer several advantages over sutures. Monofilament stainless steel staples offer less risk of infection than even the least reactive suture.\(^49\) The time necessary to accomplish closure may be significantly lessened. Acceptable wounds must be linear and subjected to weak skin forces. Wounds requiring accurate approximation of tissue are not candidates for staple closure. Staples are also uncomfortable while in situ and on removal. Stapled wounds gain tensile strength sooner, and the staples can be removed 1 to 3 days earlier than sutures. After removal, the staples should be replaced with wound closure tape for continued reinforcement.

Various stapling devices are available. The device must allow good visual access and flexible positioning for difficult angles. A pre-cocking mechanism is necessary to allow the physician to hold the staple securely during its placement. The angle of staple delivery is important. One brand releases the staple perpendicular to the wound with its crossbar flush with the skin; this can result in cross-hatching on the skin or tissue strangulation if placed too deeply. The device needs an ejector spring for smooth staple release and must be able to be handled without producing fatigue.

**Tissue Adhesives.** European and Canadian physicians have used tissue adhesives (butyl-2-cyanoacrylates) for many years. In 1998, octyl-2-cyanoacrylates were approved for use in the United States.
States. Tissue adhesives offer many advantages over traditional sutures. The emergency clinician can apply the adhesive quickly and easily with a minimum of patient discomfort. In addition, suture removal in 7 to 10 days is unnecessary, because the adhesive sloughs off the skin in approximately the same amount of time. Evidence indicates that adhesives not only provide their own dressing but also have antibacterial properties and may decrease the rate of wound infections. Closing wounds with adhesives is less expensive than traditional suturing and carries no risk of needle-stick injuries.

Tissue adhesives achieved cosmetic results similar to those of traditional sutures in randomized trials. Tissue adhesive may be applied in high-tension areas, but only if used in conjunction with subcutaneous or subcuticular sutures. If used alone, tissue adhesives are not recommended for lacerations longer than 4 cm or in areas of higher tension or frequent repetitive movements, such as joints or hands.

Other disadvantages of tissue adhesives include the inability to use antibacterial or other petroleum-based products on the wound; the recommendation not to swim, to limit forces that may prematurely remove the adhesive; and the greater risk of dehiscence. The tensile strength of tissue adhesives is significantly less than that of sutures. Despite these disadvantages, tissue adhesives represent a tremendous advance in the management of routine uncomplicated lacerations in non-tension areas. Patients routinely prefer tissue adhesives over traditional sutures.

Application of tissue adhesive begins with routine skin and wound preparation. The area must be dried and adequate hemostasis achieved before application of the adhesive. The wound margins are approximated as meticulously as possible, and care should be taken to prevent adhesive from getting between the wound margins. Applying tape (Steri-Strips) before application will facilitate wound margin approximation and make it easier to apply with similar results. Adhesive between the wound margins delays healing and increases the likelihood of wound dehiscence. The adhesive is applied to the entire length of the wound sufficient to cover 5 to 10 mm of skin adjacent to the margins. A single layer of adhesive is adequate if the current formulation is used. The adhesive sets in roughly 95 seconds. Special care is taken to ensure that the adhesive does not run off and disturb adjacent tissues. Having the patient lie on the affected side will help prevent contamination of the eye near the wound and the opposing eye. Newer, high-viscosity formulations are now available that help limit this risk. Wounds may get wet but should not be immersed in water and should be blotted dry and not vigorously rubbed. An additional dressing may be desired by the patient but is not necessary.

**Antibiotic Prophylaxis**

Routine antibiotic prophylaxis for simple wounds has no scientific basis. A meta-analysis compared the rates of infection in patients with simple non-bite wounds receiving antibiotics with those in control groups. Of 1734 patients enrolled in the seven studies, patients treated with antibiotics had a slightly greater incidence of infection. The authors concluded that prophylactic antibiotics had no role in simple non-bite lacerations. Routine antibiotic use has obvious known complications, such as increasing resistance to antibiotics, gastrointestinal side effects (nausea, vomiting, *Clostridium difficile* colitis), and allergic reactions that are common and may result in significant morbidity and unnecessary cost.

Although irrigation and debridement are the most important means of preventing wound infections, antibiotic prophylaxis is recommended in some very limited circumstances. Prophylaxis must be tailored to each patient. Some recommendations are supported by scientific data, whereas others have few data to support their use and are based on established practice standards.

**Contamination, Crush, and Host Factors**

Antibiotic prophylaxis is often provided for patients with wounds with gross contamination, patients with severe crush injuries, and immunocompromised patients. Some authors recommend not closing these wounds and instead using delayed primary closure. If circumstances require wound closure despite the infection risk, many emergency clinicians recommend prophylaxis despite scarce data.

Some authors believe that a patient with significant crush injury requires antibiotics. Crush injuries are high-risk wounds because they produce more devitalized tissue. A definitive answer may not be forthcoming, because it would be difficult to complete a well-controlled prospective, blinded study.

Patients with certain risk factors have increased wound infection rates. Large prospective studies of patients with surgical wounds showed an increased rate of wound infection in patients with diabetes, obesity, malnutrition, chronic renal failure, advanced age, and chronic steroid use. Because of higher rates of infection, some authors suggest the use of antibiotics in these patients, again based on individual circumstances. No controlled studies of antibiotic prophylaxis in these patients exist, however. Finally, some authors advocate prophylaxis for other host factors, such as prosthetic joints or risk for endocarditis. Little evidence exists to support either recommendation.

**Open Fractures, Joint Wounds, and Gunshot Wounds**

Wounds that involve joints or open fractures necessitate use of prophylactic antibiotics. Prospective randomized controlled studies have documented decreased infection rates in patients receiving antibiotics compared with placebo. Indeed, the time to antibiotic administration in these wounds was found to be the most important factor in decreasing wound infection rates.

Open fractures without evidence of significant soft tissue damage (avulsions and crushed or devitalized tissue) necessitate use of antibiotics for 24 hours. Open comminuted fractures or fractures with significant tissue damage necessitate 72 hours of antibiotics. For gunshot wounds, which are classified as a type of open fracture, the recommendations vary with the type of missile wound. Low-velocity missile wounds not treated with antibiotics showed no increased infection rate in a randomized controlled trial of 67 patients with fractures treated with a closed technique. High-velocity wounds with fracture, on the other hand, are associated with an increased risk of infection, and antibiotic therapy should be initiated early and maintained for 48 to 72 hours. In addition, patients with shotgun wounds with fracture should receive prophylaxis as well. Appropriate antibiotic therapy would be a cephalosporin with or without an aminoglycoside plus penicillin (to cover *Clostridium* species). Use of cefazolin (Ancef) 1 g every 8 hours and clindamycin 600 mg intravenously (IV) every 8 hours may be considered. For the severely contaminated wounds, tobramycin 1 mg/kg every 8 hours is added. Some recent data has proposed limiting aminoglycoside use altogether and only using cefazolin for Gustilo grade I/II open fractures and ceftriaxone for grade III open fractures. A single institution study showed little difference in infection rates after limiting aminoglycoside administration for open fractures.

**Bites and Puncture Wounds**

Antibiotics are indicated for through-and-through intraoral lac-
erations, cat bites, some dog bites, some human bites, and some puncture injuries to the foot. Of all mammalian bites, school age children account for almost half of all patients in this category, and 70% of animal bites are from pets or animals known to the victim (also see Chapter 54).
Cat Bites. Prophylaxis is required for patients with cat bites, especially bites to the hand. These bites tend to be deep puncture wounds that are difficult to irrigate adequately. These wounds also tend to become infected at a much higher rate than other types of bites. Cat bites have been reported to cause infections in 10% to 40% of all wounds. In one study, 13% of patients had signs of infection when they visited the ED, and 16% eventually developed infection. Other authors report that 80% of these bites become infected, although obvious selection bias limits this interpretation. Antibiotics seem to decrease the incidence of infection but a Cochrane review on mammalian bites suggested the limited literature on cat bites did prove antibiotic efficacy, except in hand bites. At this time, we still advocate for antibiotic prophylaxis in cat bites.

The organisms found in cat bites include *Staphylococcus* species, *Streptococcus* species, and, most often, *Pasteurella multocida*. *P. multocida* is usually found in infected cat bite wounds and is present in the normal oral flora of 70% of all cats. *P. multocida* is sensitive to penicillin, but the infection is often polymicrobial. *P. multocida* is resistant to dicloxacillin, cephalixin, and clindamycin, and there are many erythromycin-resistant strains. Amoxicillin with clavulanate (875 mg bid for 7 days) is the current recommendation for antibiotic prophylaxis for cat bites.

Dog Bites. Antibiotic prophylaxis for dog bites is more controversial. The infection rate has been reported as 6% to 16% for patients not receiving antibiotics. Dog bites tend to involve more crush injuries with tearing and avulsions rather than puncture wounds. As such, dog bites are usually more amenable to irrigation and débridement. Seven of eight randomized trials of dog bite wounds showed no benefit with antibiotics. However, pooled data for meta-analysis did show a small but statistically significant benefit from antibiotics. It may be logical to limit the use of antibiotics to high-risk wounds, such as hand injuries, deep puncture wounds, and wounds in older or immunocompromised patients.

Hand Bites. In addition to the previous bite wound recommendations, antibiotic prophylaxis of injuries to the metacarpophalangeal joints is advised. These wounds are assumed to be human bites until proved otherwise. Also known as “fight bites,” these wounds have a high incidence of infection. Patients without signs of infection may be managed as outpatients. Close inspection after anesthesia has been applied is necessary to thoroughly evaluate the area for tendon involvement and/or penetration of the joint. If the joint is involved, irrigation is required. In some institutions, all these patients are taken to the operating room for a thorough washout. Patients with early signs of infection are admitted for intravenous antibiotics and débridement and irrigation. The choice of antibiotics reflects the predominant organisms of hand bite infections. *Streptococcus* and *Staphylococcus* species are common, but *Eikenella corrodens* and *Bacteroides* species are also typical pathogens. Because *Eikenella* is often resistant to clindamycin, first-generation cephalosporins, and erythromycin, patients with early infection are treated with amoxicillin with clavulanate. Patients with later infection are treated with intravenous extended-spectrum antibiotics (eg, ampicillin with sulbactam).

**Intraoral Lacerations.** Lacerations of the oral mucosa involve bacteria-rich oral secretions and may become infected slightly more often (6% to 12%) than other wounds. Rates of infection for through-and-through lacerations may be twice the rates for simple mucosal lacerations. Although few data suggest a clear indication for prophylactic antibiotics, one study showed that patients benefit from antibiotics if they are compliant with their regimen. Another study looked at all the literature (four studies) on antibiotics in intraoral lacerations and found the

studies do not conclusively show a benefit to giving antibiotics in these types of wounds. It may be reasonable to limit antibiotic use to high-risk patients with through-and-through wounds. Penicillin 500 mg bid for 5 days is an appropriate choice of antibiotic.

**Puncture Wounds of the Foot.** Puncture wounds of the foot are seen frequently in the ED. These wounds are often caused by common carpentry nails, although other objects (eg, glass, metal, and wood) must be considered. Despite their simple appearance, these wounds may produce significant morbidity. The infection rate for puncture wounds has been reported to be 15%. Most wounds occur on the plantar surface, from the neck of the metatarsal to the toes. Simple cellulitis accounts for half of these infections. More significant infections include septic arthritis, abscesses, and osteomyelitis. *Pseudomonas* organisms cause 90% of osteomyelitis cases from puncture wounds. No data suggest a benefit from prophylactic antibiotics, but given the high risk of infection and serious complications, their use may be considered in select puncture wounds. *Pseudomonas* organisms should be suspected when the puncture went through a rubber-soled shoe is essential. Patients with puncture wounds to the foot require early follow-up. Ciprofloxacin is the drug of choice to treat outpatients with suspected wound infection when *Pseudomonas* is of concern. Cephalixin (Keflex) or dicloxacillin is adequate for staphylococcal and streptococcal coverage unless meticillin-resistant *Staphylococcus aureus* (MRSA) is likely. In cases suspicious for MRSA, sulfamethoxazole-trimethoprim or doxycycline is recommended.

**Drains, Dressings, and Immobilization**

**Drains**

Drains probably have no role in ED wound care. In general, drains are placed when a collection of fluid exists or may develop. The presence of a drain reduces the wound’s resistance to infection, regardless of the materials used in its construction, and the use of drains should be avoided. In wounds likely to collect fluid (eg, around the elbow or knee), it is preferable to place the extremity at rest with a plaster splint or perform delayed primary closure.

**Dressings**

Various dressing materials are available. The microenvironment created by a dressing affects the biology of healing. The optimal wound climate must not interfere with the activity of fibroblasts and macrophages. The production of granulation tissue and migration of epithelial cells across the wound must be optimized.

**Intraoral Lacerations.** Lacerations of the oral mucosa involve bacteria-rich oral secretions and may become infected slightly more often (6% to 12%) than other wounds. Rates of infection for through-and-through lacerations may be twice the rates for simple mucosal lacerations. Although few data suggest a clear indication for prophylactic antibiotics, one study showed that patients benefit from antibiotics if they are compliant with their regimen. Another study looked at all the literature (four studies) on antibiotics in intraoral lacerations and found the
Films are thin membranes that are transparent, adhesive, and waterproof but are not absorptive. They are best reserved for wounds with low levels of drainage. Film dressings may be left in place for up to 7 days, as long as they do not leak or separate from the wound bed. For wounds with a moderate amount of drainage, moderately absorbent hydrocolloid dressings may be indicated. These dressings are thicker than films, semiocclusive, waterproof, and very comfortable for the patient. Like films, they can be left on for up to 7 days. Foam dressings are more absorptive and made of a soft cushion sponge-like material. Some may require a secondary dressing for adhesion and need to be removed every 3 days. Hydrogel dressings are moisture-donating water-based gels that are available in sheets attached to a semi-permeable film. These dressings do not absorb fluids, so they must be used on relatively dry wounds. Patients often find these dressings to be the most comfortable, but they need to be changed every 1 to 3 days. The least expensive and simplest method of dressing a straightforward, uncomplicated laceration is to use Vaseline-impregnated gauze or gauze on top of a thick layer of antibiotic ointment. These should be changed daily to prevent desiccation.

**Immobilization**

Wounds in proximity to joints must be immobilized as part of routine care. Splinting the injured body part places the injury at rest and hastens healing. Failure to splint appropriately exposes the healing tissue to the dynamic forces of muscular contractions, ultimately slowing the healing process and increasing scar size. In addition, immobilization decreases lymphatic flow and minimizes spread of microflora from the wound.

**DISPOSITION**

**Wound Care Instructions**

It is difficult for patients to identify and recognize the signs of infection (Box 52.2). Discharge instructions must be clear, understandable, and reasonably comprehensive. Instructions should include daily care, observation for signs of infection, suture removal dates, and a follow-up source. It should be recommended to the patient that injured extremities be elevated during the first 24 to 48 post-traumatic hours and explained that elevation lessens edema, hastens healing, and mollifies pain. The wound should be protected as described previously or cleaned daily to remove crust formations. It is safe for patients to bathe and get the wound wet 24 hours after injury. Daily swabbing with half-strength hydrogen peroxide rids the wound of debris and any blood clot that forms between the sutured edges. Hydrogen peroxide should not be used after separation of the scab, because it is toxic to the epithelium and may produce bullae.

Wound infection is difficult for the untrained observer to distinguish from the inflammatory response of injury and subsequent healing. Patient education in this regard should be cautious and straightforward (eg, return or seek follow-up for redness, swelling, increased pain, fever, pus, or red lines progressing up an extremity). An injury classified as high risk must be reexamined 48 hours after the trauma, regardless of its appearance. Discharge instructions should include highlighting the possibility that a foreign body may be present despite efforts to remove it. Return precautions outlining signs of wound infection are essential.

Suture removal times vary, but generally they are approximately 4 days for the face and 7 to 14 days for other body parts (see Box 52.2). Considerations include cosmetics, dynamic forces in proximity to the injury, static skin tension, blood supply, and anticipated healing rates.

**Tetanus Immunization**

The incidence of tetanus in the United States is rare with only 233 cases reported during the 2001 to 2008 surveillance period with a case fatality rate of 13.2%. Most tetanus patients in the United States are older than 50 years old. Immunization status needs to be considered in all patients with wounds, regardless of severity. Forty percent of all cases of tetanus occur in individuals who have either minor wounds or no recollection of injury. These numbers raise serious questions regarding the validity of separating immunization recommendations according to clean and tetanus-prone wounds. Studies show that many people are inadequately immunized, especially patients older than 70 years, immigrants, and people with no education beyond grade school. Also, patient immunization histories are often unreliable. Given the inability to predict which wounds are at high risk, all wounds are approached with suspicion.

The usual incubation period for tetanus is 7 to 21 days (range, 3 to 56 days). Immunization is given as soon as possible but can be given days or weeks after the injury. The dose of tetanus toxoid (T) or diphtheria, pertussis, and tetanus toxoids (DTaP) is 0.5 mL intramuscularly, regardless of the patient’s age. Inadequately immunized patients need a dose of DTaP and tetanus immune globulin (TIG). The TIG dose is 250 IU for all ages 7 years old or older and 4 IU/kg IM up to 250 IU for ages younger than 7 years old (Table 52.1). A single injection of TIG provides protective levels of passive antibodies for at least 4 weeks. The immune globulin and toxoid may be given during the same visit but should be administered with a different syringe at separate sites. The literature suggests that emergency clinicians need to be more diligent administering TIG, because it is often not provided when indicated.

Because studies suggest that 10% to 40% of the population in the United States is inadequately immunized against pertussis, pertussis vaccination is recommended along with tetanus toxoid. Immunity to pertussis wanes approximately 5 to 10 years after vaccination. Since the 1980s, the number of reported pertussis cases has steadily increased, especially among adolescents and adults. Children younger than 11 years old should receive the DTaP immunization. In 2005, a tetanus toxoid, reduced

**BOX 52.2**

**Wound Care Instructions**

I. Elevate the injured extremity above the level of the heart. Wear a sling when appropriate.
II. Cleanse daily in a gentle manner to remove debris and crusting that develops. Use dilute hydrogen peroxide.
III. Immobilization should be maintained at least until suture removal.
IV. Signs of infection
   A. Redness
   B. Increasing pain
   C. Swelling
   D. Fever
   E. Red streaks progressing up an extremity
V. Wound check
   A. As needed to check signs of infection
   B. Routine at 48 hours for high-risk wounds
VI. Suture removal (Note: Suture may be removed earlier if Steri-Strips reinforce the wound.)
   A. Face: 3 to 5 days (always replace with Steri-Strips)
   B. Scalp: 7 to 10 days
   C. Trunk: 7 to 10 days
   D. Arms and legs: 10 to 14 days
   E. Joints: 14 days
**TABLE 52.1**

Tetanus Prophylaxis for All Patients With All Wounds\textsuperscript{a,b}

</tbody>
</table>

\textsuperscript{a}All injections are intramuscular.

\textsuperscript{b}Consider more frequent immunization for elderly patients. Tdap recommended for ages 11 to 64 years old (Adacel, Sanofi Pasteur) and 65 years old and older (Boostrix, GlaxoSmithKlineBiologicals), although both products likely effective in the older than 65 age group.

\textsuperscript{c}Refer these patients to complete their series; DTaP in 6 weeks and 12 months.

Diphtheria toxoid, and acellular pertussis vaccine, adsorbed (Tdap) product formulated for use in adults and adolescents was licensed in the United States for people 11 to 64 years old. Updated recommendations allow for Tdap (Boostrix, GlaxoSmithKlineBiologicals) to given to patients 65 years old and older, although it is likely that either Adacel or Boostrix vaccine will provide protection.\textsuperscript{17} When possible, it is recommended that this triple combined formulation be used in the ED for tetanus prophylaxis of adolescents and adults. Although all four injections (T, diphtheria and tetanus toxoids [DT], TIG, and DTaP) are considered safe and effective in pregnancy, because of limited experience during pregnancy the recommendation is to use DT. However, DTaP is recommended immediately postpartum, including for breast-feeding women.

Box 52.3 summarizes the principles of wound care management.

**BOX 52.3**

**Summary of Wound Care**

I. Stabilize patient
II. History (include tetanus immunization and allergies)
III. Physical examination
   A. Neurovascular examination
   B. Anesthesia: Bupivacaine 0.5% without epinephrine, regional or local
   C. Bloodless field: Tourniquet or sphygmomanometer for extremities
   D. Thorough examination of anatomic structures, skin, nerves, tendons, blood vessels, bones, muscles, fascia, other (ducts, cartilage)
   E. Consultation if indicated
IV. X-ray films to detect injury to bone or the presence of foreign bodies (plain films, CT or ultrasound)
V. Wound preparation
   A. Cut—do not shave—surrounding hair
   B. Prepare surrounding skin with a chlorhexidine-alcohol solution
   C. Sharp débridement of foreign matter and devitalized tissue
   D. High-pressure irrigation with saline or a 1% povidone-iodine (Betadine) solution
VI. Wound closure
   A. Tape, staples, or suture
   B. Do not use subcutaneous sutures unless the wound is under high tension
VII. Antibiotics
   A. Apply topical antibiotics
   B. No systemic antibiotics unless wound is very high risk
VIII. Dress and immobilize: Consider a transparent gas-permeable dressing
   A. Wound care instructions (see Box 52.2)
      1. Signs of infection
      2. Elevation
      3. Wound check if necessary
      4. Suture removal as soon as possible

**KEY CONCEPTS**

- Risk factors for wound infection include crush mechanism; long (>5 cm) deep penetrating wounds; high-velocity missiles; diabetes; and contamination with saliva, feces, soil, or other foreign matter.
- The most effective intervention to decrease infection is thorough cleansing, with use of saline or tap water irrigation at approximately 8 psi. Attaching an 18-gauge needle to a 35-mL syringe creates an irrigant force of 7 or 8 psi, which decreases bacterial counts.
- Soaking wounds in povidone-iodine (Betadine) is more toxic than beneficial to healthy tissue. Prepare the skin with a chlorhexidine-alcohol solution.

- Antibiotics are indicated for through-and-through intraoral lacerations, cat bites, some dog bites, some human bites, puncture injuries to the foot in high-risk individuals, open fractures, and wounds involving exposed tendons or joints.
- High-risk wounds should not be sutured primarily but may be repaired in 4 or 5 days (ie, delayed primary closure).
- Tetanus immunization should be provided soon after injury but can be given days or weeks later. The usual incubation period for tetanus is 7 to 21 days (range, 3 to 56 days).
- Tdap is recommended for patients 65 years old or older requiring tetanus prophylaxis.
CHAPTER 52: QUESTIONS & ANSWERS

52.1. Which of the following is associated with an increased risk of infection?
A. Avoidance of epinephrine use in wound anesthesia
B. High-pressure irrigation
C. Use of clippers instead of razors for hair management near wound
D. Use of silk suture material
E. Use of tape over sutures for wound closure

Answer: D. Silk yields the highest infection rates, whereas monofilament synthetic substances have the lowest risk of infection.

Risk Factors for Wound Infection

1. Injury more than 8-12 hours old (varies depending on the following factors)
2. Location: leg and thigh, then arms, then feet, then chest, then back, then face, then scalp
3. Contamination with devitalized tissue, foreign matter, saliva, or stool
4. Blunt (crush) mechanism
5. Presence of subcutaneous sutures
6. Type of repair: risk greatest with sutures > staples > tape
7. Anesthesia with epinephrine
8. High-velocity missile injuries

52.2. A 32-year-old man presents with 20 stab wounds to his arms and legs after sustaining an assault. He weighs 80 kg. Which of the following is an appropriate dosage of wound anesthesia?
A. 240 mg of 1% lidocaine
B. 320 mg of 0.5% bupivacaine
C. 400 mg of 0.5% bupivacaine with epinephrine
D. 700 mg of 1% lidocaine with epinephrine

Answer: A. In adults, the maximal reported safe dose of bupivacaine is approximately 2.5 mg/kg without epinephrine and 3.5 mg/kg with epinephrine, assuming the injection is a wound infiltration technique and not one in a highly vascular area. General dose guidelines for lidocaine are 3 and 5 mg/kg without and 5 to 7 mg/kg with epinephrine, respectively. A 1% lidocaine solution contains 10 mg/mL. The actual percent solution does not matter; the total milligram dose does.

52.3. A 23-year-old female presents with a laceration to her thigh. As you begin to apply anesthetic, she tells you that when she went to the dentist she had an allergic reaction to procaine. Which of the following should you use?
A. Benzocaine
B. Benzocaine with epinephrine
C. Bupivacaine
D. Lidocaine from a multidose vial
E. Tetracaine

Answer: C. Allergy to local anesthetics is uncommon. Two distinct groups of “caine” anesthetics exist. The esters include procaine, tetracaine, and benzocaine. The second group, including lidocaine and bupivacaine, belongs to the amide family. Allergy to the esters is uncommon. True allergy to agents in the amide family is rare. No cross-reactivity occurs between the amide and ester families, so an agent from a different group may be chosen. A “preservative-free” preparation should ideally be used because the para-aminobenzoic acid in multidose vials may cause an amine-like reaction that may be confused with an allergy to the primary agent.

52.4. Which of the following is most likely to require no antibiotic prophylaxis?
A. Cat bite
B. Diabetic with contaminated wound
C. Dog bite
D. Human bite
E. Puncture wound through rubber sole

Answer: C. Antibiotic prophylaxis is often provided for patients with wounds with gross contamination, patients with severe crush injuries, and immunocompromised patients. Prophylaxis is also required for patients with cat bites. Seven of eight randomized trials of dog bite wounds showed no benefit with antibiotics. Human bites or lacerations to the metacarpophalangeal (MCP) joint are termed “fight bites,” and these wounds have a high incidence of infection. Thus, of the choices given, dog bites have the lowest incidence of infection and therefore are the least likely to require prophylactic antibiotics.

REFERENCES

52.5. Antibiotic coverage of a cat bite must target which of the following pathogens?
A. Bacteroides species
B. Clostridium perfringens
C. Eikenella corrodens
D. Pasteurella multocida
E. Pseudomonas species

**Answer:** D. The organisms found in cat bites include *Staphylococcus* species, *Streptococcus* species, and, most often, *P. multocida*. *P. multocida* is usually found in infected cat bite wounds and is present in the normal oral flora of 70% of all cats. *P. multocida* is sensitive to penicillin, but the infection is often polymicrobial. *P. multocida* is resistant to dicloxacillin, cephalaxin, and clindamycin, and there are many erythromycin-resistant strains. Amoxicillin with clavulanate is the current recommendation for antibiotic prophylaxis for cat bites.

52.6. A 74-year-old patient presents with a gaping wound from a dog bite, complaining of pain at the site. The dog belongs to a friend, has reportedly had “all his shots,” and is in custody. The patient is from Central America but has lived in the United States for more than 50 years; he does not recall his immunization history. Besides copious irrigation and wound dressing, which of the following should be included in the treatment of this patient?
A. Diphtheria, pertussis, tetanus toxoids (DTP) and tetanus immunoglobulin (TIG)
B. Rabies immunization
C. Tetanus toxoid
D. Tetanus toxoid and immunoglobulin
E. B and D

**Answer:** A. Studies show that many people are inadequately immunized, especially patients older than 70 years old, immigrants, and people with no education beyond grade school. Patient immunization histories are often unreliable. Given the inability to predict which wounds are high risk, all wounds should be approached with suspicion. Inadequately immunized patients need a dose of DTP and TIG. Because studies suggest that 10% to 40% of the population in the United States is inadequately immunized against diphtheria, diphtheria vaccination should be given along with tetanus toxoid. Many adults are not immunized against pertussis, and the incidence of disease has been rising since the 1980s. In 2005, a new acellular form of the pertussis vaccine became available and is recommended for all adults.
CHAPTER 53

Foreign Bodies

Stephen H. Thomas | Jeffrey M. Goodloe

PRINCIPLES

Patients often present to the emergency department (ED) with a complaint of a retained foreign body. The anatomical locations vary and may determine the management, emergent removal, and need for subspecialty referral or surgical removal under general anesthesia. Patients may be forthright with a complaint of a foreign body, but in some cases information may be withheld due to embarrassment.

Clinical Features

When people ingest or insert foreign bodies, often a brief history may be sufficient to establish the diagnosis, guide initial management decisions, and predict the process required for definitive removal. Those at higher risk of having a foreign body include neurologically impaired patients, edentulous individuals, patients with certain psychiatric diagnoses, incarcerated individuals, and individuals at the extremes of age. In these same groups, definitive history is often elusive, and the emergency clinician has to rely upon situational clues.

Depending on the location of the foreign body, the physical examination can provide direct or indirect evidence of the object. Specifics are described in the following sections, but there is a recurring theme, which is meticulous examination frequently establishes the correct diagnosis, as well as suggesting a successful extraction method.

Differential Diagnoses

Even when patients are fully cooperative, the diagnosis of foreign body can be complicated by the fact that patients can be unaware of the object’s presence. Although foreign body cases are usually not diagnostic dilemmas, the emergency clinician should keep in mind the possibility of “foreign body mimics” such as angioedema.1

Diagnostic Testing

Plain radiography is classically the primary imaging modality that yields foreign body detection and characteristics of location, size, and number. Even when objects are not visualized, radiographs may show secondary changes (e.g., pulmonary air trapping) providing clues to foreign body presence.2 To assist in the localization, two views—anteroposterior and lateral—are usually necessary. Metallic objects are usually easy to visualize on plain radiography. For non-metallic (e.g., organic) material with density similar to that of human tissue, visualization requires alternative imaging, such as ultrasound, magnetic resonance imaging (MRI), or computed tomography (CT).3-5

Management

Extraction is indicated in most cases. A discussion with the patient (or appropriate surrogates) should outline the benefits and risks of the anticipated course for foreign body removal. Sometimes a foreign body represents an immediate life threat, as is the case with an airway obstructing foreign body, and the need for urgent extraction action takes precedence. Even without overt life threats, some foreign bodies require expeditious removal. For instance, illicit drug leakage can kill a body packer, an impacted button battery can cause fatal tissue perforation and hemorrhage, or an otic insect can cause intense pain and damage sensitive ear structures.6-8 Foreign bodies may serve as a nidus for infection that is recurrent or refractory to antibiotic therapy; definitive resolution only occurs with identification and removal. Specific recommendations for foreign body removal are presented in the following sections outlining management considerations by anatomic location.

Disposition

Most patients can be safely discharged home following uncomplicated foreign body removal. Retained foreign bodies may need surgical specialty follow-up, such as in an outpatient setting. Depending on anatomic location and patient ability to cooperate, some retained foreign bodies require surgical intervention under general anesthesia.

EYE

Principles

The diagnosis usually is self-evident. Ocular trauma without proper eye protection is the most common history.3,10 Foreign bodies are occasionally identified by abnormal ocular examination findings without a stated history of trauma. For example, the cause of reduced vision in an intoxicated patient may be a foreign body (Fig. 53.1). Early diagnosis, care, and follow-up minimize risks, such as endophthalmitis or sight-threatening siderosis bulbi.5,11

Clinical Features

Most patients report a foreign body sensation, even though they cannot see the foreign body. The patient may complain of frequent lacrimation and conjunctival reddening. Foreign bodies that have created corneal injury and are no longer present may account for symptoms identical to those noted with a retained foreign body. Occasionally, patients with retained foreign bodies (such as, malpositioned contact lenses) can present with recurrent conjunctivitis.12

An important component of the history is whether radial keratotomy or similar ocular surgery has been performed. Historically, ophthalmologic procedures (such as, radial keratotomy) have been reported to be associated with increased potential for delayed-diagnosis foreign body entrapment.13 Although more current literature contains little or no mention of these procedures as foreign body risk factors, the potential for situational
Computed tomography (CT) scan shows right intraocular foreign body (BB pellet) in intoxicated patient without known trauma history.

Differential Diagnoses

Selected differential diagnoses of ocular foreign bodies include corneal abrasions, conjunctivitis, iritis, glaucoma, allergic chemosis, and globe perforation.

Diagnostic Testing

If the history and mechanism of injury are compatible with ocular penetration by radiopaque material, or if a small wound of the globe is noted, anteroposterior and lateral radiography of the orbit is a reasonable initial step to evaluate for deeper penetration into the globe (see Fig. 53.1). Given its advantages in depicting small ocular foreign bodies and complications such as globe rupture, CT is the best initial approach, especially when there is strong suspicion of intraocular penetration. CT has the additional utility of imaging of the intracranial compartment, which is often indicated in cases in which ocular trauma has occurred.

When globe penetration is strongly suspected, fluorescein is best avoided because its application can obscure findings in subsequent physical examination. Fortunately, the incidence of intraocular perforation in the setting of low-velocity (non-explosive) exposures is low. One case series of 288 patients reported a near-zero incidence of intraocular foreign body in patients with corneal metal foreign bodies after low-velocity exposures. When perforation is judged unlikely and fluorescein is administered, identification of rivulets of fluorescein tracking from a puncture (ie, positive Seidel test) is helpful in identifying intraocular penetration.

Ultrasound is a useful adjunct to CT scanning in patients with foreign bodies that are difficult to localize. For patients in whom a foreign body is suspected despite negative ED evaluation, outpatient referral to ophthalmology should be executed because CT, ultrasound, and even MRI have all missed ocular foreign bodies in patients who subsequently developed complications. Given the paucity of reported case series and justifiable concerns about eye damage from mobilization of ferromagnetic foreign objects, use of MRI for ophthalmologic foreign body imaging remains controversial. When there is any chance of metallic object presence in the eye, the emergency clinician should not order MRI without consulting both ophthalmology and radiology specialists.

Management

In nearly all cases, therapy is removal of the ocular foreign body. If the object is located on the bulbar or palpebral conjunctiva (not the cornea), it often can be removed easily by sweeping the site with a moist cotton-tipped applicator. For small corneal foreign bodies, after application of topical ocular anesthesia, it is often necessary to use an eye spur or small-gauge tuberculin syringe needle to move gently underneath one end of the object and flick it out. It is prudent for the emergency clinician to avoid significant motion or hearing buzzing. As compared to insect foreign bodies

Disposition

If attempts at foreign body removal are not indicated or are unsuccessful, the patient should be referred to ophthalmology for object removal within 24 to 48 hours. Ophthalmology referral should be initiated after removal of metallic foreign bodies because there may be subtle retained fragments or rust rings requiring removal.
in the nose or throat, those in the ear are far more likely to be living (and moving). Less specific complaints include itching, discharge, or otalgia. Similar secondary symptoms may be present when non-insect foreign bodies are within the ear canal. Nonspecific presentations are common in children, who can be fearful of reporting a foreign body. The child presents only when there are secondary problems (such as, purulent discharge) from the affected ear.

If the ear canal foreign body erodes into the middle or inner ear, complications may range from malocclusion to eustachian tube dysfunction and serious infections (such as, mastoiditis and meningitis). Although these situations are infrequent, recent literature outlines risk entailed with impression material (eg, silicone) used for indications, such as molding of hearing aids.

History should include home attempts at foreign body removal. Such efforts may have caused problems, such as ear canal trauma or tympanic membrane perforation.

The cylindrical external auditory canal has two anatomic points of narrowing (and, thus, foreign object lodging). The first point is near the inner end of the cartilaginous portion of the canal and the second is at the point of bony narrowing called the isthmus.

Adequate lighting and an appropriately sized otoscope are essential to optimizing the visual search for otic foreign bodies. With any examination involving the external auditory canal, grasp the pinna of the ear and retract it in a posterosuperior direction to straighten the canal. This maneuver affords a more complete view of both the canal and the tympanic membrane.

If the tympanic membrane has been ruptured by the foreign object or by prior removal attempts, documentation should indicate the presence of rupture before ED attempts at foreign object removal. As in other body locations, the risk of multiple foreign objects warrants consideration.

### Differential Diagnoses

The selected differential diagnoses of ear foreign bodies include otitis media, otitis externa, ear canal trauma, tympanic membrane perforation, Ménière’s disease, and otologic tumors.

### Diagnostic Testing

Diagnostic imaging is rarely required in otic foreign bodies. CT or MRI may be performed to characterize infectious or erosive sequelae.

### Management

The treatment for otic foreign bodies is their removal, which should usually occur in the ED. Success rates for ED removal of ear canal foreign bodies vary with patient population and constituent foreign body types.

Even in a very young patient, presence of a foreign body for more than 1 or 2 days does not constitute an independent risk factor for foreign body removal failure or complication. In the absence of clear contraindications (eg, obvious tympanic membrane rupture), the emergency clinician should proceed with otic foreign body removal efforts, even in children with objects in the ear canal for a few days.

The patient should be informed about the extreme sensitivity of the auditory passage and the likely discomfort and potential for minor bleeding. Lidocaine instillation may aid in topical anesthesia; liquid 1% or 2% solution is preferred to gel preparations, which impair subsequent visualization.

Infrequently, foreign body removal requires local anesthesia of the external ear canal. The anesthesia instillation procedure may cause patient discomfort and iatrogenic injury if not performed with care (and patient control). The procedure entails injecting all four quadrants of the canal with lidocaine via a tuberculin syringe inserted through an otic speculum. Given complexity of local anesthesia to the canal, systemic procedural sedation and analgesia may be preferable.

When the ear canal is inhabited by an insect, it is important to kill or immobilize the creature to facilitate its removal. Any of a number of agents can be used to kill the insect. Topical anesthetics are recommended, and hydrogen peroxide should be avoided because of risk of injury to inner ear if there is tympanic membrane perforation. Efficacious formulations include lidocaine as a 10% spray or less concentrated liquid, 2% lidocaine gel, mineral oil with 2% or 4% lidocaine, and alcohol.

Immobilization reduces the chance of patient discomfort or ear damage caused by an insect attempt to evade forces introduced into the ear canal. Patient comfort may also be optimized by minimization of shining light into an ear canal inhabited by light-avoiding insects (such as, cockroaches).

Several extrication methods may prove effective and various instruments may be useful. With soft or irregularly shaped objects, it is often possible to grasp the foreign body with forceps (alligator forceps are usually best) and remove it either in one piece or in fragments. If the object cannot be grasped, it may be possible to remove it by passing a blunt-tipped right-angle hook beyond the foreign body and gently coaxing it out. Alternatively, a balloon-tipped catheter can be passed distal to the object, with subsequent attempts to withdraw the (inflated) balloon, extracting the object. Any balloon-tipped catheter design may be used, as long as its caliber is small enough (about 18-gauge or smaller) to allow comfortable introduction into the ear canal.

Irrigation techniques take advantage of the elliptic shape of the external ear canal. A stream of lukewarm or room-temperature water or saline should be directed at the foreign body’s periphery via a 20-mL syringe and a 14- or 16-gauge catheter; this arrangement has been studied in the laboratory and demonstrated to generate pressures that are well below those required to perforate the tympanic membrane. Irrigation should not be used if there is known history, clinical suspicion, or physical examination evidence of tympanic membrane perforation.

Removal of objects from the middle ear with cyanoacrylate adhesive-tipped swabs is not recommended and carries the risk of contaminating the ear canal with a substance that is difficult to remove and has been associated with ear canal and tympanic membrane injury. When cyanoacrylate has been instilled into the ear, acetone instillation is recommended to facilitate its safe removal.

Removal of otic foreign bodies must be undertaken with care and steadiness. Patient apprehension and sudden movements can risk untoward foreign body movement and avoidable damage to the ear canal.

Otic foreign body sequelae are usually not serious. There are sporadic reports, usually related to missed diagnoses and persistent ear canal objects, of serious complications ranging from chronic otitis to hearing loss, facial palsy, and deep-seated infections, such as mastoiditis. The most common complications include external ear canal bleeding (10%), otitis externa, and (in about 2% of patients) tympanic membrane perforation. Complications are more likely when the otic foreign body has been in place for prolonged periods, when patients are unable to be cooperative with removal attempts, and when practitioners are less experienced.

After removal of the foreign body, the canal examination is repeated to ensure the lack of retained material and to evaluate otic anatomy. In cases in which the tympanic membrane is ruptured and the middle ear is at risk for infection, appropriate oral and topical antibiotics are recommended.
Disposition

If ED methods of removal are unsuccessful, the patient should be referred to an otolaryngologist within a week. More urgent referral is recommended for cases in which the tympanic membrane is ruptured, or in cases where foreign body removal proves particularly traumatic (in such cases the follow-up is aimed at assessing for external otitis).

Differential Diagnoses

The select differential diagnoses of nasal foreign bodies include nasal polyps, septal hematomas, nasal tumors, infectious and allergic rhinitis, and anterior and posterior epistaxis.

Diagnostic Testing

Diagnostic imaging does not usually play a major role, although plain radiography is important when there is suspicion for a metallic foreign body, such as a button battery. When intranasal foreign bodies are suspected, CT can be helpful. The potential risk of MRI for detection of foreign bodies may become more relevant with increasing frequency of foreign bodies related to magnetic jewelry (ie, nose rings and studs).

Management

The emergency clinician is highly successful at removal of nasal foreign bodies and is only rarely a need for subspecialty consultation and operating room removal. Foreign bodies that have eroded into the sinus space are an obvious exception to the rule of ED removal; admission for endoscopy in the operating room is recommended in such cases.

Occasionally, positive pressure applied to the patient’s mouth by a parent or relative achieves rapid foreign body dislodgment while obviating the need for restraint, sedation, and other requirements attendant to more invasive removal techniques. The underlying principle is that a short burst of air blown into the mouth of a child, with finger occlusion of the nonobstructed naris, may force the foreign object out of the nose. Insufflation, preferably applied a mouth-to-mouth maneuver from a parent, can also be provided by a manual ventilation bag (with a pop-off valve to prevent pressure rising above 30 mm Hg) or similar positive-pressure device.

Insufflation may be self-applied. Children can be instructed to take a deep breath and blow hard through their nose, as a parent closes the unaffected naris.

When insufflation is not warranted or is unsuccessful, ear, nose, and throat instruments and removal techniques may be required. Regardless of the method, the patient (usually a child) may benefit from some combination of restraint, sedation, and pretreatment with vasoconstrictive agents (eg, nebulized racemic epinephrine) and anesthetic (eg, benzocaine spray). Adequate illumination is essential. Depending on the nature of the foreign object, necessary instruments include a blunt-tipped right-angle probe, suction catheter, and alligator forceps. The forceps are used when the foreign body is to be directly grasped, and the right-angle probe is used in an attempt to reach behind the foreign object and displace it forward.

Other useful instruments include Fogarty (vascular) and Foley catheters; commercially available “specialized” balloon-tipped catheters can also be used. Magnets may be useful when the intranasal foreign body is metallic and appropriately constituted. In some cases, suction can be used to withdraw foreign bodies directly. Cyanoacrylate-tipped swabs may be useful in certain circumstances, although there are obvious risks of inadvertent contact between the glue and nasal mucosa.

Disposition

Patients with a simple foreign body presentation for whom the object is easily removed, do not require special follow-up. In cases where the nasal foreign body was in place for an extended period of time, or in cases for which removal was difficult or traumatic, otolaryngology follow-up in 24 to 48 hours should occur to assess for postextraction complications.

AIRWAY

Principles

Background and Importance

Children and the elderly are at high risk for foreign body aspiration. Most airway foreign body patients are younger than 9 years old, and there is a decline in incidence as mastication is facilitated by emergence of permanent teeth. In adults, the elderly are at significant risk because of the presence of comorbidities such as neurological and dental conditions.
The most common airway foreign bodies vary with the particular case series, and the case report literature includes an array of respiratory tract objects ranging from dental appliances to turban pins and wall plugs.\textsuperscript{3}–\textsuperscript{40} In most series, food items are commonly aspirated as are medications.\textsuperscript{30,41}

Diagnostic delay is associated with increased complications in all patient age groups.\textsuperscript{42,43} One pediatric study identified a doubling of complication rates with presentations delayed beyond 48 hours.\textsuperscript{44} Patients with altered mental status from a variety of causes are at heightened risk for occult aspiration. Even in large-series reports of aspiration, the elusive nature of specific and reliable indicators of airway foreign body presence means that a concerning history should prompt a diligent foreign body search.\textsuperscript{30,42,45}

### Anatomy and Pathophysiology

Foreign bodies can be located as proximally as the oropharynx, with retained objects having been found in the palatal and pharyngeal mucosal regions.\textsuperscript{46,47} Foreign body impaction at the laryngeal or subglottic level often is caused by inappropriately executed attempts to finger-sweep an oropharyngeal foreign body.

Airway foreign bodies that pass beyond the laryngeal inlet may cause complete obstruction. Foreign bodies passing beyond the carina are less likely to cause acute hypoxia because there is an unobstructed contralateral airway. Right-sided bronchial aspiration is the more common location because the carina is positioned right of the midtrachea in 40% of infants, and the proximal right bronchus is both wider and more steeply angled than the left.\textsuperscript{47}

Foreign objects can be bilateral, and the rule for airway foreign bodies mirrors that for other foreign bodies: when one object is identified, there should be a search for a second.

### Clinical Features

Clinical presentation can range from chronic nonspecific respiratory complaints to acute airway obstruction.\textsuperscript{48} In one series of ambulance-transported airway foreign body patients 50% suffered cardiopulmonary arrest prior to ED arrival.\textsuperscript{48} In most aspiration cases, foreign body presence can be suspected after a thorough history. Patients with airway foreign bodies may have noisy breathing, inspiratory stridor, vomiting, and hemoptysis.\textsuperscript{49}

Some patients may give a history, known as the penetration syndrome, including a choking sensation accompanied by wheezing and coughing.\textsuperscript{50} Coughing may not eject the foreign body completely but rather results in its impaction in the subglottic region. Therefore, coughing after suspected aspiration should prompt a search for a foreign body even if the symptoms improve.

In pediatric patients with suspected foreign body aspiration, sudden onset of choking or intractable cough associated with wheezing and respiratory distress is present in over 63% of cases.\textsuperscript{46} In addition to coughing and choking, stridor is frequent.\textsuperscript{51} Absence of early cough and choking is correlated with delayed diagnosis and chronic presentations (eg, recurrent pneumonia).\textsuperscript{34,52,53}

With sudden onset of dyspnea and odynophagia, an impacted subglottic object may be present. If the object is known to be sharp and thin, the emergency clinician should suspect embedding between the vocal cords or in the subglottic region with resultant partial obstruction.

Other components of the history can help diagnose and characterize foreign bodies in patients with aspiration of nonfood objects. Many types of items may be aspirated by children who are exploring their environment. Another at-risk population comprises individuals who normally “store” small items in their mouths for quick access; examples of the latter include construction workers (nails) and seamstresses (pins).

Trauma patients with injured and loose teeth may have aspirated in the field or during emergency laryngoscopy for oral intubation. The incidence of airway aspiration of avulsed teeth or prosthetic dental appliances is low (0.5% of 1411 facial trauma patients), but both the initial trauma and subsequent airway management pose risks.\textsuperscript{33} In some cases (such as, penetrating or blast trauma), the patient may be unaware of the potential for aspiration and not attribute symptoms to this entity. Patients aspirating objects that are long and thin (eg, needles, hatpins) may have minimal or no symptoms other than mild cough or chronic hemoptysis or odynophagia.\textsuperscript{39}

The child with respiratory difficulty after eating can represent a diagnostic dilemma. Children with stridor or other respiratory symptoms may have airway foreign body aspiration or esophageal bolus impaction with external compression of the trachea. The pediatric trachea is soft, especially posteriorly, and may be compressed by a large esophageal body pressing anteriorly on the trachea. In addition, the trachea itself may be displaced anteriorly and kinked, causing a partial obstruction. Fever and localized infection may indicate bony aspiration (eg, into the piriform fossa) that may occur when bone-containing foods are fed to very young children.\textsuperscript{52} Unfortunately, missed esophageal foreign bodies in children can result in wheezing and stridor from fistula formation; the result is long-term, yet mistaken, diagnosis and treatment for asthma.\textsuperscript{56}

The presentation of patients with a retained airway foreign object may include only infectious complications. A foreign object may cause retropharyngeal abscess. A patient with atypical or recurrent pneumonia may have pulmonary infection secondary to persistence of a foreign object serving as a nidus of infection.

Physical findings depend on degree of airway obstruction and duration of the object’s presence. Depending on size and location of the foreign body, the examination may show a normal patient, one with cyanosis and respiratory arrest, or anything in the range between these two extremes.\textsuperscript{57,58} There are some useful findings. Unilateral diminution of breath sounds, present in over a third of cases in one large pediatric series, may help diagnose an aspired foreign body.\textsuperscript{59} Patients may be stridorous or hoarse with upper airway foreign objects, and intercostal or sternal retractions may be noted in patients with high-grade obstruction from tracheal foreign bodies. Hypoxemia may be present. Patients with secondary infection may have fever.

Oropharyngeal examination may reveal a foreign body posteriorly or “donor sites” of fractured teeth. The examination should include a search for fractured or missing dental prostheses. Oropharyngeal examination frequently can be augmented by indirect or direct laryngoscopy or nasopharyngoscopy, but these procedures should be performed only if the procedural stress does not pose undue risk of airway compromise.

Coughing may result from local irritation caused by bronchial foreign bodies. Localized or apparently generalized wheezing is frequently auscultated in patients with lower respiratory tract foreign bodies.\textsuperscript{7} Complete obstruction of a mainstem bronchus may be associated with absent ipsilateral breath sounds; however, breath sounds can be transmitted across the thorax and the only physical abnormality may be asymmetric chest rise. Occasionally a foreign body acts as a one-way valve, allowing air into the lung during inspiration but permitting none to exit during expiration. The involved lung becomes hyperexpanded, and this finding may be detected as hyper-resonance to percussion.

### Differential Diagnoses

The selected differential diagnoses of airway foreign bodies include anaphylactic reactions, acute pharyngitis, acute epiglottitis, retropharyngeal abscess, neck tumors, pulmonary carcinomas, pneumonia, bronchitis, bronchiolitis, and tuberculosis.
Diagnostic Testing

The main reason to characterize the type of airway foreign object is to determine the likelihood of radiopacity. Imaging decisions are informed by understanding whether a foreign body’s constituent material is likely to be radiopaque.

Most airway foreign bodies are not visible with plain films. In 3149 aspirated foreign body cases, 84% of airway foreign bodies consisted of organic material (usually nuts) difficult to see on x-rays. Nearly half of fatal choking cases in children are a result of radiolucent food aspiration. In the stable patient, plain radiography of the neck and chest remains the mainstay of initial airway foreign body imaging. Air trapping may be visible when inspiratory and expiratory films are compared but more recent literature casts doubt on the clinical necessity for adding expiratory views to plain radiography. Decubitus chest x-ray positioning does not offer significant benefits to standard radiographs of the chest.

A normal radiograph cannot rule out an aspirated foreign body in a patient with a suggestive history. Studies of series of patients who underwent endoscopy with confirmed foreign body aspiration demonstrate both low sensitivity and poor specificity.

Specific findings on plain radiography are categorized as direct (ie, identification of the foreign body itself) or indirect (eg, hyperinflation). Radiographic findings are indirect in most cases, with hyperinflation and emphysema being far more common than pneumothorax.

If doubt exists as to the radiopacity of the suspected foreign body, and if the patient has brought a piece of the object, it may be tested for radiodensity by placing it over the shoulder during taking of the radiographs. When subglottic foreign body impaction is suspected, plain soft tissue radiographs of the neck are the best initial step, provided that they are performed under the close supervision of a physician trained in airway management. Negative plain radiographs are not diagnostic, but clear identification of an airway foreign body can provide a rapid diagnosis leading to admission for endoscopy.

Indirect or secondary signs, such as subglottic space narrowing (from an embedded foreign object), are an important aid in foreign body radiography. Air trapping and atelectasis are the most common early clues to airway foreign body presence, with bronchiectasis and pneumonia developing later. In air trapping, a comparison of inspiratory and expiratory films shows a flat, fixed diaphragm on the involved side, and the heart and mediastinum shift to the uninvolved side during expiration (Fig. 53.2). In one classic pediatric series, air trapping was found in 90% of patients with lower airway foreign bodies, but subsequent years’ clinical experiences confirm that the indirect signs of airway foreign body are easily missed on initial x-ray readings. If obstruction becomes complete, the involved lung becomes atelectatic and pneumonia can develop; patients with persistent atelectasis or pneumonia should have foreign objects considered as the explanation. An additional indirect radiographic sign of more proximal foreign bodies is prevertebral swelling or soft tissue emphysema seen on neck films.

In a stable patient when a foreign body is seen on the chest radiograph but its airway-versus-esophageal location is in doubt, the anteroposterior orientation of the object may help (Fig. 53.3). Esophageal foreign bodies usually are oriented in the coronal plane, and airway objects are oriented in the sagittal plane (Fig. 53.4). X-ray films also can provide useful information by showing whether the object is within or outside of the tracheal air column (Fig. 53.5).

Advanced imaging with CT or MRI is indicated when there is high clinical suspicion and plain radiography does not provide definitive results. These imaging modalities usually require a more extended period outside of the ED, so patients must be sufficiently stable for movement to the CT or MRI suite.

CT or MRI benefits include characterization of extra-airway anatomical complications, such as perforation or bleeding. Visualization of a foreign body by advanced imaging can also eliminate a step in foreign body evaluation, allowing elimination of diagnostic flexible bronchoscopy in favor of movement directly to therapeutic rigid bronchoscopy for foreign object retrieval.

In usual practice, CT tends to be more rapidly accessible in most EDs, so CT is the advanced imaging modality that is most useful for foreign body searches. The role for MRI tends to be in diagnosis of foreign objects that are radiolucent (eg, nuts with high fat content).

CT (and less commonly, MRI) offers an additional utility—virtual bronchoscopy. Multidetector imaging provides a three-dimensional view of the tracheobronchial airway with proven utility in respiratory foreign body cases. One of the largest series...
CT virtual bronchoscopy should be considered when clinical suspicion is high and initial radiography is nondiagnostic. Fluoroscopy was historically useful in airway foreign body evaluation. This modality has been supplanted by other advanced imaging techniques (eg, CT, bronchoscopy).

Management of an airway tract foreign body is removal, which generally leads to rapid recovery of the patient. When the foreign object is distal to the oropharynx, subspecialty consultation is the safest means for foreign body removal. In rare cases, even oropharyngeal foreign bodies (such as, small needles) may necessitate subspecialist consultation and operative removal. As a general

rule, early consultation with an otolaryngologist to perform bronchoscopy in any patient with a suspected foreign body is key to reducing morbidity and mortality; the role of endoscopic management remains important given limitations of other diagnostic methods.59

In a patient with critical airway obstruction and impending or actual respiratory arrest, the emergency clinician must act quickly to identify and remove the foreign body. There are generally three options: (1) attempt to extract the foreign body with maneuvers, (2) perform laryngoscopy or fiberoptic nasopharyngoscopy with attempts at removal under direct visualization, or (3) control the patient’s airway. If at all possible, emergent consultation with other specialties who can assist in advanced airway management is imperative (eg, otolaryngology, anesthesiology, surgery).

Oropharyngeal foreign bodies may be removed with use of pediatric or adult Magill forceps after visualizing the foreign body in the mouth. Blind finger sweeps should never be performed to remove a foreign body.

The basic life support management of a choking infant includes up to five back blows with the patient in a head-down position, followed by chest thrusts. In children, the Heimlich maneuver may be considered in the choking but conscious patient. In children who are unconscious, chest compressions are begun in cycles of five and the oropharynx visualized between cycles to see if the foreign body has been expelled into the mouth. If basic maneuvers fail to dislodge the foreign body allowing removal from the mouth, direct laryngoscopic visualization followed by removal of the object with Magill forceps should be performed.63 When a foreign body is not visualized on laryngoscopy, the foreign body lies below the level of the vocal cords or is in the esophagus. The emergency clinician may choose to attempt to intubate the patient to establish an airway, but this is not without significant risk.

Intubation may force the foreign body distally, especially if the endotracheal tube tip is passed beyond the carina. Placement of the endotracheal tube into the right mainstem bronchus may displace the foreign body into the right bronchus, allowing oxygenation and ventilation through the left-sided pulmonary tree when the endotracheal tube is withdrawn back to normal position proximal to the carina. If the foreign body is in the esophagus, endotracheal intubation may provide necessary stenting of the trachea to keep the airway open.

In cases in which intubation fails because of positioning of the proximal foreign object, surgical cricothyrotomy (needle cricothyrotomy in young children) is indicated. Cricothyrotomy may bypass such proximal obstruction and provide sufficient oxygenation to bridge the time gap to further definitive care by surgical subspecialists.

Patients who do not require immediate intubation or cricothyrotomy for complete airway obstruction may require airway management for other indications. These patients may have poor oxygenation, severe respiratory distress, and or hypventilation. Especially in pediatric patients requiring bronchoscopy, the laryngeal mask airway may be an appropriate approach if ED airway management is necessary.65

In noncritical situations, the only airway foreign objects generally amenable to emergency clinician removal are those in the oropharynx, which is best removed by forceps under direct laryngoscopic (including fiberoptic-facilitated) visualization performed after administration of topical anesthesia.66 Care should be taken when nonobstructing foreign objects appear to be impaled in the oropharynx because postremoval hemorrhage can occur. These should be removed in the operating room under general anesthesia. Removal of a laryngeal foreign object, even with general anesthesia, can be dangerous. Risks include hemorrhage, laryngeal trauma, and airway obstruction from the mobilized foreign object. Also, special care should be taken to prevent posterior displacement of oropharyngeal foreign objects or dropping of incompletely grasped proximal foreign bodies into the more distal airway.

The management decisions for endoscopic evaluation and treatment depend on the clinical presentation. When there is time-critical airway obstruction, rigid bronchoscopy is employed with flexible instrumentation used for diagnostic purposes in less acute patients.

Disposition

Pediatric data suggest that performance of bronchoscopy within 24 hours of initial ED presentation reduces complications by half.66 Even after foreign body removal, sequela may occur and can range from bleeding to infectious complications. Patients with a lower airway foreign body should be admitted for foreign body removal and observed for development of sequelae with postdischarge follow-up within a few days of removal of the foreign body.

GASTROINTESTINAL TRACT

Principles

Most cases of gastrointestinal foreign bodies occur in pediatric patients, but adults are also at risk particularly if they are edentulous or if there are psychiatric conditions.67,68 Higher risk is present in cases in which chemical or electrical mucosal injury is likely (eg, button battery or magnet ingestions).69 Perforation occurs in approximately 3% of cases and most frequently involves the esophagus or the ileocecal region.70

Pharynx and Esophagus

Clinical Features

Foreign bodies lodged in the pharynx and esophagus are usually a sharp object (eg, fishbone) that is impacted in the wall of the pharynx, hypopharynx, or esophagus or a larger bolus, usually a coin or food, that cannot pass beyond the anatomic points of esophageal constriction. Pediatric series report that coins are the most common culprit, comprising well over half of ingested foreign bodies.71 Esophageal constriction locations, where foreign objects tend to lodge, are (1) the proximal esophagus at the level of the cricopharyngeus muscle and thoracic inlet or, radiographically, the clavicular level; (2) the midesophagus at the level of the aortic arch and carina; and (3) the distal esophagus just proximal to the esophagogastric junction or, radiographically, a level two to four vertebral bodies cephalad to the gastric bubble. In one 15-year pediatric series, 92% of esophageal foreign bodies were impacted at the cricopharyngeal level.72 Foreign bodies may lodge at any level of the esophagus (or remainder of the gastrointestinal tract) with abnormal anatomy.

The complication rate for esophageal foreign body ingestion depends on the nature of the foreign body, the presence of impaction, and the duration of impaction. Overall, complications are rare, but there are important exceptions for perforating foreign bodies or those (eg, button batteries) that mediate chemical damage.72,73 Complications become more likely with increasing impaction time and include esophageal erosion or perforation, tracheal compression, mediastinitis, esophagus-to-airway or esophagus-to-vascular fistulae, spondylodiskitis, extraluminal migration, abscess development, and formation of strictures or false esophageal diverticula.74,75

In addition to coins, other common objects impacting the esophagus include but are not limited to food, toys, bones, batteries, wood, and glass. Esophageal rupture is a particular risk from
the button (disk) battery. These batteries cause pathologic changes through pressure, electrical current, leakage of corrosives, or heavy metal poisoning.\(^{28}\) The identification of button batteries has both prognostic and therapeutic ramifications. Esophageal button battery impaction is considered an indication for prompt endoscopic intervention and removal.\(^{73,76}\) Although not as likely as button batteries or sharp foreign bodies to cause esophageal rupture, practically any ingested foreign body (eg, meat) can cause rupture if patients vomit repeatedly after impaction.

Children usually are brought to the ED within 6 hours of foreign object ingestion. The most frequent presenting symptoms are dysphagia, drooling, retching, and vomiting. Pain, usually odynophagia, may be the major complaint. Anorexia, wheezing, or chest or neck pain also may be present.

Patients may complain that they can feel the object in the throat or chest, are unable to pass it, and are often able to localize the foreign body accurately. This presentation is particularly common if the foreign object is lodged in the upper esophagus. Dropping is consistent with high-grade obstruction.

Patients with suspected esophageal foreign body impaction rarely have complaints of shortness of breath or air hunger. When these findings are present, the emergency clinician should suspect a large esophageal foreign body impinging anteriorly and compressing the trachea. Infants and children may experience coughing, choking, croup-like symptoms, or significant respiratory compromise from foreign bodies lodged in the upper esophagus.\(^{73}\)

Patients may manifest late sequelae. Foreign bodies serving as a nidus for infection can result in complaints, such as fever. Signs of mediastinitis indicate esophageal perforation. Perforation of the esophagus with erosion into the vasculature or pulmonary tree can result in presentations ranging from hemoptysis to pulmonary abscess or life-threatening hemorrhage.

The history should include any known esophageal anatomic abnormality or prior instrumentation. A patient with a history of esophageal stenting should be considered to have stent migration when the history is dysphagia. Migration typically occurs within the first week of placement.

Examination begins with a careful inspection of the oropharynx and hypopharynx. This search may reveal the foreign body or identify an oropharyngeal mucosal scratch that can cause foreign body symptoms even in the absence of an impacted object. Oropharyngeal examination also may provide indirect clues; for example, a missing dental plate on examination should lead the emergency clinician to suspect this item as a possible gastrointestinal tract foreign object. The base of the tongue, vallecula, supraepiglottic area, epiglottis, and piriform sinus should be examined. Topical anesthesia facilitates the examination. If adequate visualization is not obtained with the indirect laryngoscopy mirror, fiberoptic nasopharyngoscopy or direct laryngoscopy may be performed.

Subcutaneous emphysema found by neck palpation indicates probable esophageal perforation.

Differential Diagnoses

The selected differential diagnoses pharyngeal and esophageal foreign bodies include acute pharyngitis, acute epiglottitis, retropharyngeal abscess, esophagitis, strictures, esophageal webs, and oral cancers. When the history is unclear, the emergency clinician should consider an ingested foreign body in the differential diagnosis of atypical chest pain, wheezing, stridor, or signs of respiratory distress.

Diagnostic Testing

The fact that most foreign bodies (eg, coins) are radiopaque accounts for reports that radiography contributes to diagnosis and management in most cases of esophageal impaction.\(^{77}\) The initial step is generally a posteroanterior and lateral chest radiograph and lateral cervical spine x-ray study using soft tissue technique. The primary utility of plain radiography lies in detection of radiopaque objects, with indirect findings (eg, soft tissue swelling) more likely of utility in cases where there are chronic foreign bodies with complications.

Overall, the sensitivity of plain radiography for detection of esophageal foreign bodies depends on the nature of the foreign body. In patients who are transferred to the ED from an outlying hospital, repeat radiography may be useful to assess whether the foreign object has passed into the stomach in the interval since prior films (Fig. 53.6).

Esophageal foreign objects usually align themselves in the coronal plane and are posterior to the tracheal air column on lateral view. Coins in the esophagus lie in the coronal position in virtually all cases because the opening into the esophagus is much wider in this orientation (see Fig. 53.3).

Certain common foreign bodies are not radiopaque. Fish and chicken bones are frequently ingested, are difficult to visualize directly or radiographically, and often scratch the esophageal mucosa. Although some studies suggest that technique variation improves fish bone detection, plain x-ray examination remains insufficiently sensitive as a means to rule out these foreign bodies and CT is recommended when initial imaging is negative.

When plain films fail to visualize foreign bodies and suspicion remains high, one option is contrast esophagography, which can be useful with radiopaque and sometimes with radiolucent foreign bodies. If perforation is not a concern, barium may be used as the contrast medium because it provides higher-quality images. If an esophageal leak is suspected, water-soluble contrast solution should be used. When initial contrast films are not definitive, patients may be asked to swallow a contrast-soaked cotton ball, which may localize the foreign body by lodging proximal to the object.
Contrast studies, even performed with barium, have limitations when the suspected object is an impacted bone. Barium swallow yields better results but risks aspiration and coats the object and esophagus, reducing effectiveness of subsequent endoscopy.

CT scans with coronal and sagittal reconstructions are useful in identifying foreign bodies or more completely characterizing objects that are only vaguely appreciated on plain films. For some suspected foreign bodies that tend to be radiolucent, CT may be the primary diagnostic modality because it can give information about foreign body size, type, location, and orientation with respect to other anatomic structures. CT also can assist with identification of complications, because it can assess extra-esophageal anatomy.

One interesting modality reported in detection of metal foreign bodies is the handheld metal detector. This modality does not involve risk or ionizing radiation, has no complications, and is quite useful with reported sensitivity approaching 90%. Especially when results are positive and indicate a foreign body below the diaphragm, or when the metal detector is used to track foreign body progress (eg, coin passage) over time, this modality can obviate the need for radiography.

Management

Pharyngeal foreign bodies visualized by direct or indirect laryngoscopy usually can be removed with forceps or a clamp. The emergency clinician should guard against the possibility of inducing trauma or airway obstruction during extraction attempts.

With an esophageal food bolus or coin, the emergency clinician may be able to provide definitive management. With sharp objects, displaced esophageal stents, or impacted button batteries, more invasive and specialty specific management is necessary. Treatment strategy depends on the nature of the foreign body, the length of time the object has been lodged, and the expertise of the clinicians managing the case. In addition, the patient’s age and prior medical and surgical history may be relevant. The overall success rate for endoscopic (ie, nonsurgical) removal of esophageal objects is very high.28 When the esophageal impaction is food, pharmacologic maneuvers are the first basic strategy for foreign body management. These steps are appropriate only if the object is known to be an impacted food bolus. The first medication that may be administered in an attempt to move a distal esophageal food bolus into the stomach is intravenous glucagon (0.5 to 2 mg). The drug appears to act by lowering the smooth muscle tone at the lower esophageal sphincter without inhibiting normal esophageal peristalsis. Glucagon’s historical efficacy of relieving esophageal food impaction in a third of cases has been confirmed in more recent series.80 It should be noted that glucagon is less effective in esophageal eosinophilic infiltration, which diagnosis may be increasingly reported by food-impaction patients presenting to the ED.80,81

Although it remains reasonable to try glucagon, the drug should be given slowly. If glucagon is given rapidly, there is theoretical risk that the induced vomiting could cause rupture of an obstructed esophagus.

Gas-forming agents have been historically used for ED treatment of impacted esophageal food bolus and this approach has little or no recent evidentiary support. These medications also incur a known risk of mucosal injury and are not recommended.

Two other agents, nitroglycerin and nifedipine, have been historically used for distal food bolus impaction but are not as useful as glucagon and thus not recommended for use in the ED. Both of these agents have a relaxing action on the lower esophageal sphincter, yet they appear only marginally effective as therapy for impacted food bolus. A last approach, enzymatic degradation of an impacted meat bolus by use of the proteolytic enzyme papain, has fallen into disfavor because of risks of esophageal perforation.

The preferred strategy for impacted esophageal foreign body removal is, in most cases, early endoscopy.82 Flexible endoscopy is the optimal early course for a variety of esophageal foreign bodies, including coins. The procedure does not require general anesthesia, can be performed in a sedated (nonintubated) patient, and may be diagnostic and therapeutic.81

The final strategy for foreign body removal, bougienage, involves pushing the foreign object into the stomach. The emergency clinician is generally not responsible for patient selection or actual performance of this procedure.

Expectant management, hoping for spontaneous foreign object passage into the stomach, is often successful. This approach is best suited for patients seen within 24 hours of ingestion who have a radiographically identified “safe” object (eg, small coin) in the distal esophagus.

Disposition

If a disk battery or magnetic object has been ingested, the location must be ascertained. If lodged in the esophagus, ED consultation should be directed toward emergent removal by endoscopy. If the object has passed distal to the esophagus, observation may be appropriate but the high risk of these cases dictates involvement of appropriate gastrointestinal consultants in management decisions.89

Regardless of the method used for esophageal foreign body therapy, there should be a follow-up evaluation of esophageal anatomy and patency after the removal of any esophageal object. Referral for such evaluation should be made by the emergency clinician.

Stomach and Bowel

Principles

Foreign bodies that reach the stomach (Fig. 53.8) rarely cause major difficulties, although problems may occur, such as perforation and infection (eg, after occult fish bone ingestion).83 Objects may still become impacted, most often at the gastric outlet or the ileocecal valve, although complications can arise at any point throughout the intestinal portion of the gastrointestinal tract. The increasing frequency of pediatric magnet ingestions is contributing to an increasing complication rate seen with gastrointestinal foreign objects.92

Clinical Features

Symptoms of intraluminal objects range from none to vague abdominal pain to obstruction or perforation-associated peritonitis. Most patients have a specific history of ingested items.

Hiding of illicit drugs is a relatively frequent motivation for foreign body ingestion. Rupture of these drug-containing packages, especially when cocaine is involved, can result in rapid, lethal consequences.84 Less often, such packages can cause bowel obstruction. Even when obstruction is not present, vomiting may be reported. Body packing, which entails systematic gastrointestinal tract placement of previously prepared drug packages (Fig. 53.8), should be clinically differentiated from body stuffing, which denotes hurried ingestion of hastily prepared packages in the face of imminent police presence. Due to the poorly organized wrapping of illicit drugs, body stuffers are more likely to experience toxicity and less likely to have well-delineated findings on plain radiography. Drugs most often seen with body packing or body stuffing are cocaine and heroin.
Another important component of the history is medical implants in the gastrointestinal tract. Dental hardware and biliary stents are among the implants that can migrate and cause complications in the distal gastrointestinal tract.85,86

Patients with gastrointestinal tract foreign bodies should be asked about history possibly related to bezoar presence. A habit of chewing hairs can result in trichobezoars, which infrequently extend from the stomach into the small intestine as a “tail” (Rapunzel syndrome). Phytobezoars (composed of vegetable matter) and lactobezoars (from milk curds) also have caused complications, usually in the stomach. Other bezoars may be composed of infectious material (eg, fungal bezoars) or inorganic substances (eg, lithobezoars). Ingested toothpicks can lodge in the bowel wall, causing gastrointestinal complications and erosions or compression of nearby structures.87

If the foreign body is a bezoar (a mass of indigestible food or nonfood material), there may be a palpable mass on abdominal examination. Physical findings may also include abdominal examination abnormalities typical of bowel obstruction or peritonitis.

**Differential Diagnoses**

The selected differential diagnoses of stomach and bowel foreign bodies include peptic ulcer disease, gastroesophageal reflux disease (GERD), gastric outlet obstruction, gastric tumors, bowel obstruction, intestina polyps, and small and large bowel carcinomas.

**Diagnostic Testing**

Because most ingested foreign bodies are radiopaque, the initial imaging modality of plain radiography is often diagnostic (Figs. 53.9 and 53.10; see Fig. 53.6).88 Even when suspicion is low, radiography can identify foreign bodies as the explanation for symptoms. Two-view plain radiography has proved useful for situations ranging from coin ingestion to body packing (see Figs. 53.6 and 53.8).

The sensitivity of plain radiography varies widely, depending on the nature of the foreign material. When plain films are non-diagnostic, follow-up contrast radiography or CT is recommended. Contrast administration for some CT-delineated foreign bodies can identify the objects and assess for complications, such as perforation.89

In the setting of body packing or body stuffing, the preferred CT imaging approach is avoidance of oral contrast, but even this approach has been reported to have sensitivity of well under 50%.
for either detection or enumeration of packs. Ultrasound is useful in drug packet cases in which plain radiography is nondiagnostic, when there is need for an initial screening test, or when previously identified packets need to be tracked without ionizing radiation. Negative ultrasound results are nondiagnostic.

Management

The general rule for the management of gastric or intestinal foreign bodies is observation, with radiographic and stool follow-up to confirm passage. As is the case with esophageal impactions, more referral centers are reporting early endoscopy as a useful approach due to the modality’s low risk and high efficacy. However, for the routine cases (eg, coin ingestions) encountered by emergency clinicians, most ingested objects are expected to pass spontaneously if patients have normal anatomy.

Management decisions are based in part on the nature of the ingested object. Blunt objects can be expected to pass through the bowel with expulsion verifiable by stool collection and examination. If there is particular concern, serial radiographs may be obtained after a week. Sharp objects (such as, needles) may be recovered via endoscopy, but consultants (with whom all sharp gastrointestinal foreign bodies should be discussed) may decide to manage these cases expectantly. Early removal generally is required for objects wider than 2 cm because they do not pass the pylorus or longer than 5 to 6 cm because they do not clear the duodenal sweep. Overall, surgery is rarely required in intestinal foreign body cases, but there will be cases (eg, bowel obstruction) in which clinical circumstances prompt early operative intervention.

When chosen, observation should be continued until (1) the object is found in the patient’s stool; (2) the object becomes associated with bowel obstruction or perforation, necessitating immediate surgical intervention; or (3) the object shows no evidence of progression through the gastrointestinal tract on two radiographic examinations performed 24 hours apart, indicating impaction and need for active removal.

In a body packer or body stuffer (see Chapters 149 and 156), regardless of law enforcement pressures, the emergency clinician should perform only interventions justified medically as reasonable steps to prevent injury from the ingested object or substance. If emergent drug package retrieval is medically unwarranted, the patient should be admitted for close observation for package passage or signs of toxicity. Monitoring drug metabolites in the urine may be helpful. Usually the package passes through the gastrointestinal tract spontaneously. This passage can be facilitated with polyethylene glycol solution, laxatives, or both. Immediate removal of drug-containing packages should be considered if the patient develops intestinal obstruction or drug intoxication. Endoscopic removal of drug-containing packages is associated with theoretical risk due to package rupture and drug intoxication, but endoscopy remains a therapeutic mainstay in patients who are not passing ingested packets spontaneously.

Button batteries and magnets represent an additional group of foreign body types with specific management implications. Intact objects of this category that are ingested and pass into the stomach can be observed without the immediate removal necessary in cases of esophageal impaction. Administration of polyethylene glycol solution may speed distal movement. If the foreign body has not been passed after the first few clear-liquid stools, repeat radiography may identify objects in the rectum, where they may be digitally evacuated. The emergency clinician should obtain early consultation (for endoscopy or surgery) when button batteries or magnets are encountered in the gastrointestinal tract, because the complication rates with these objects are higher than for other foreign bodies. Available evidence is insufficient to confirm usefulness of adjuvant medications (eg, steroids, antireflux agents, prophylactic antibiotics) in cases of button battery ingestion.

Disposition

For button battery or magnet ingestions that are managed expectantly, repeat radiographs should be taken the next day to ensure movement of the object into the intestinal tract. X-rays should be repeated at least every 3 to 4 days thereafter to confirm continued distal movement. Management of other foreign bodies and bezoars depends on type and location. Infants with lactobezoars should be changed to elemental diets with close follow-up; most cases resolve without surgery.

Rectum

Principles

Most anorectal foreign bodies result from retrograde introduction, typically as a result of sexual practices. Prompt diagnosis is crucial because delay in definitive treatment is strongly associated with complications.

Clinical Features

Patients with anorectal foreign bodies are often hesitant to provide accurate histories. Studies have found that many patients with self-introduced anorectal foreign bodies do not freely admit to insertion but rather report anal pain or simply constipation. Other complaints include rectal pain, bleeding, or inability to void when large objects impinge on the urethra. It is possible for ingested food or objects (eg, fish bones) to lodge in the rectum after passing through the proximal gastrointestinal tract. The duration for which the object has been in the anorectum has implications for mucosal failure and rupture. Patients with anorectal perforation may have findings of peritonitis or abdominal tenderness. On digital rectal examination, the foreign body might be directly palpated; this is the method of diagnosis in a large number of cases. In the absence of direct
foreign body palpation, digital rectal examination may reveal findings (eg, bloody discharge, loose sphincter tone) that raise suspicion for anorectal foreign body.102

When the digital rectal examination findings are negative or when better visualization is required, anoscopy is the next step. Although the anoscope’s diameter limits the size of foreign bodies that may be extracted through the instrument, anoscopy affords an improved view of the object’s nature and positioning. Rigid sigmoidoscopy may be performed, with special care taken to minimize pressure on possibly ischemic anorectal mucosa.

In many patients, especially patients in whom multiple examinations or removal attempts have been made, sedation and analgesia may be required to enable invasive examination techniques. When there is any doubt about the integrity of the anorectal mucosa, invasive examination is best done in the operating room with use of general anesthesia.102,103

Differential Diagnoses

The selected differential diagnoses of rectal foreign bodies include internal and external hemorrhoids, anal fissures, rectal and anal tumors, perirectal and anal abscess, and rectal vault stool impaction.

Diagnostic Testing

With rectal foreign bodies, the history usually renders imaging unnecessary unless there is a need to assess for complications, such as perforation or abscess. When diagnostic radiography is needed, plain films are recommended as the initial step and will often demonstrate the foreign body (Fig. 53.11, see Fig. 53.9). An important secondary finding on plain films is free intra-abdominal air secondary to anorectal perforation. If the object is not visualized on plain x-ray studies, a contrast study can be performed, with care taken to minimize hydrostatic pressures on potentially compromised mucosa. Water-soluble contrast should be used if perforation is suspected. CT should be employed to provide defining detail when plain films are nondiagnostic or if complications (eg, perforation) are suspected.104

Management

With patience and judiciously administered procedural sedation and analgesia, the emergency clinician often can remove rectal foreign bodies. Surgical intervention may be necessary on occasion. Depending on the nature of the foreign body and the presence of damage or perforation of the rectal wall, transanal removal (with or without sedation and local anesthesia) is successful in roughly half of patients.103 Some advocate early triage of patients for operating room removal if ED foreign body extraction carries undue risk of anal sphincter injury.106 The emergency clinician should not attempt to retrieve objects that pose high risk for rectal injury (eg, light bulbs).

Initial efforts at foreign body removal in the ED should begin with the examiner’s digit. Small rectal objects occasionally can be hooked by the finger and withdrawn. The digits should be lubricated with lidocaine jelly, and gentle abdominal pressure may be applied posteriorly and inferiorly in an attempt to mobilize foreign objects distally.

When digital extraction fails, the emergency clinician should attempt to use an anoscope or small vaginal speculum to visualize the foreign body. Ring forceps are placed through the visualizing apparatus to grasp and remove small objects. Sometimes the mucosa may become tightly adherent to the distal end of the foreign body, creating a vacuum that prevents object withdrawal. Passage of a Foley catheter beyond the foreign object (sometimes via a rigid sigmoidoscope) with proximal air inflation of the catheter balloon usually breaks the vacuum and permits retrieval. When the emergency clinician possesses the appropriate expertise and equipment or if consultants are available, the next step may be removal with a vacuum device that is well-suited for some foreign bodies or forceps; sigmoidoscopy may be a necessary adjunct to such an approach. As with other removal means, the physician should be careful to minimize risk of anorectal perforation. Caution should be used when enemas or cathartics are administered to patients with known rectal foreign bodies, especially foreign bodies with sharp edges.

An assessment for rectal injury is indicated after removal of the foreign object. When foreign body retrieval has been simple and the patient does not show increased pain, tenderness, or rectal bleeding, further imaging or direct visual evaluation for rectal trauma is unnecessary. Appropriate antibiotics are indicated in all cases of suspected bowel wall perforation and peritonitis.

Disposition

If any signs or symptoms of pain or rectal bleeding are present, postremoval sigmoidoscopy may identify small abrasions requiring close follow-up with a gastrointestinal or colorectal specialist. In general, hospitalization is indicated if emergent surgery is needed or if a rectal laceration or perforation is found.

GENITOURINARY TRACT

Principles

The literature describes a wide variety of genitourinary tract foreign objects, ranging from easily extracted tampons and condoms to penile rings removed with great difficulty. As is the case with other foreign body locations, the genitourinary tract has also been the site at which a variety of odd foreign objects have been reported (eg, radio antennae, electric cables).107,108

Clinical Features

The patient history has major value in diagnosis of most genitourinary objects, because these are often placed by the patient or
in immunosuppressed patients or in patients with diabetes mel-
Candida bezoar. Fungal bezoars are usually, but not always, seen
with adenitis, neurogenic bladder, antibiotic use, or an indwelling urinary
boude to physicians’ attention. Migration of both physician-
purulent discharge. Secondary symptoms also can bring foreign
sizing the need for an accurate history.

Often, no imaging is necessary and the foreign body’s contours
when urethral or bladder radiopaque foreign bodies are suspected.
Plain radiography also has proved useful in unusual cases of
embedded metallic objects that may be difficult to palpate due to
regional swelling and tenderness on palpation.

Ultrasound is useful to investigate for hydrenephrosis. Acous-
tic shadowing may not be seen, depending on the nature of the
foreign body; Candida bezoars lack acoustic shadowing. These
bezoars and other genitourinary tract objects are generally iden-
tifiable on CT.115,116 Urethrocytography and cytourethroscopy may
be useful tools for the urologist identifying and locating genito-
urinary tract foreign objects.

Genitourinary tract foreign bodies may be infectious. The term
bezoar, traditionally considered to delineate indigestible material in
the gastrointestinal tract, also has been used (along with uro-
bezoar) to describe foreign material collections throughout the
urinary tract.14-116 One common urinary tract bezoar is the
Candida bezoar. Fungal bezoars are usually, but not always, seen
in immunosuppressed patients or in patients with diabetes mel-
litus, neurogenic bladder, antibiotic use, or an indwelling urinary
catheter.116,217

Patients of all ages require a careful, gentle examination due to
frequent anxiety about the anatomic region being examined. In a
pediatric patient, a nasal speculum may be used to help visualize
a vaginal foreign body. Thorough vaginal examination is indicated
in patients with symptoms of vaginitis, with the search directed
for infectious agents and foreign bodies. A vaginal foreign body
may be palpated during digital rectal examination.

In children and adults, the presence of blood or discharge at
the urethral meatus or vagina should be noted. Patients with
intraurethral foreign objects also may have perineal induration
and a high incidence of associated infection, which may progress
to sepsis. In males with penile shaft swelling, the emergency cli-
nician should perform careful inspection for constricting objects.
In any child (including an infant) with penile or labial swelling, a
coronal constricting hair should be sought.118,119

In patients with retained penile rings, especially in those cases
presenting after some hours’ delay, examination often will reveal
a swollen penis with mottling, duskniness, and excoriation. The
interruption of venous and lymphatic outflow results in increas-
ing penile enlargement with risks of tissue damage. Damage is
especially likely if there have been previous attempts—as is usually
the case—by the patient at self-removal of the constricting device.
Examination may reveal indirect evidence of other genitourinary
objects as well (e.g., multiple abscesses from embedded metal
objects).120

Differential Diagnoses

The selected differential diagnoses of genital urinary tract foreign
bodies include urethritis, urethral strictures, penile tumors, penile
hematomas and priapism, vaginitis, cervicitis, Bartholin cysts, and
retained products of conception.

Diagnostic Testing

Management

Vaginal foreign bodies usually are removed easily. If the object has
been present for some time, there may be associated bacterial or
fungal infection. This should be treated with appropriate antimi-
crobials (e.g., metronidazole 500 mg three times daily for a week
for bacterial infection; fluconazole 150 mg in a single oral dose
for candidal vaginitis).

In males or females, foreign bodies located just inside the ure-
thal meatus usually can be grasped with a clamp and removed.
After failure of one or two attempts at removal by the emergency
clinician, the best course is early urology consultation. Objects
located in the proximal urethra or bladder usually require cystos-
copy for extrication. One exception is the Candida bezoar, which
generally is treated with antifungal agents. Penile urethral foreign
bodies may be associated with urinary retention and secondary
infection; in these cases, early urology consultation for endoscop-
ical intervention is necessary.

Constricting penile foreign bodies are removed as early as possi-
because progressive swelling makes removal more difficult.
Sedation and analgesia may be necessary. Also, care should be
taken when removing constricting objects with instruments such
as ring cutters, because penile shaft lacerations may be easily
cased due to tautness of the thin underlying skin. Hair and string
foreign bodies are removed relatively easily with forceps and scis-
sors or scalpel.

Disposition

After penile ring removal and confirmation of ability to void,
patients usually can be discharged with close follow-up. Consulta-
tion with a urological specialist should be obtained for patients
with penile trauma. Vaginal tears secondary to foreign body inser-
tion or extraction may require admission and emergent gyneco-
lurgical surgery.

SOFT TISSUES

Principles

Soft tissue foreign bodies present unique diagnostic and manage-
ment dilemmas. Foreign bodies may be present not only in
patients with known wounds but also in patients with secondary
symptoms who are unaware or uncertain of foreign body entry.

Clinical Features

All patients with wounds should be considered for soft tissue
foreign body contamination. In straightforward cases, patients
have symptoms such as pain or foreign body sensation and may
specifically report a foreign body. Meticulous examination and
use of diagnostic aids are in order when the patient is certain of
a foreign body not readily seen by the emergency clinician. Par-
icularly for radiolucent objects, such as wood splinters, the
history and patient sensation are used as a guide to exploration.
In more difficult cases, patients have symptoms related to complications. Soft tissue infections, especially if recurrent, should suggest a foreign body serving as a nidus. A careful history in patients with soft tissue complaints should include a search for antecedent trauma, no matter how remote, that may have resulted in foreign body entry.

The diagnosis is frequently obvious on visual inspection or standard wound evaluation. For smaller objects, use of magnification may be a significant aid in foreign body identification and removal. In addition to location of the foreign body, the examination should address injuries collateral to the object’s presence. Distal neurovascular function should be tested.

**Differential Diagnoses**

The selected differential diagnoses of soft tissue foreign bodies include skin infections, arthropod bites, lipomas, ganglion cysts, melanoma, and basal and squamous cell carcinomas.

**Diagnostic Testing**

Depending on the nature of the foreign object, anteroposterior and lateral radiographs of the involved area of the body can be diagnostic. Plain radiography has been shown to be more than 98% sensitive when the foreign body is metal or other radiopaque material, such as gravel. If silver nitrate sticks were used to achieve hemostasis before imaging, the deposited metal can be expected to appear on plain radiography.

One common foreign body is glass, which is usually radiopaque. The size glass that will be seen on x-rays depends on composition and alignment, but it appears that about 0.5 mm is the cross-section above which glass should be visualized on plain films. Not seen easily on plain radiographs are items such as vegetable material (eg, wood) and plastic.

Xeroradiography, recommended in the past, has fallen out of favor. This technique has no clearly demonstrated advantage over plain films and has been discarded in favor of other modalities. This technique has no clearly demonstrated advantage over plain films. Not seen easily on plain radiographs are items such as gravel, glass, and metals.

Fluoroscopy has received attention as a diagnostic and therapeutic tool. Against the risks attendant to higher doses of ionizing radiation (especially when compared to ultrasound), fluoroscopy offers long-proven ability to facilitate identification and complete removal of foreign objects.

When plain radiographs are negative and suspicion for a foreign body remains, ultrasound or CT is the next step. Ultrasound is readily available in many EDs and has been the subject of intensive study and the technique continues to evolve. With use of a 10-MHz or 7.5-MHz probe for shallow depths and a 5-MHz probe for deeper searching, ultrasound is clearly useful when positive. The main imaging findings in a series of sonographic imaging of non-radiopaque foreign materials in 47 patients were hyperechoic foci (96% of cases) and posterior acoustic shadowing (77% of cases); a halo sign indicating infection (fluid around the foreign body) was seen in 11%.

Overall, given the availability of ultrasound in the ED and the multiple case reports of its occasional utility in foreign body localization and removal, it is reasonable to employ this technique with the understanding that a positive test result is much more useful than a negative one. In specific situations, ultrasound may even be the best available imaging modality. For example, B-scan ultrasound as performed by ophthalmologists is better than both CT and MRI for identification of wooden foreign bodies in the posterior segment of the eye.

In addition to characterizing objects seen on plain films, CT may prove useful for items (eg, plastic, wood) missed on plain radiographs. CT may also prove valuable in localizing small or deep objects. CT also is useful for identifying foreign body sequelae (eg, abscess). For objects such as gravel, glass, and metals, MRI streaking can hamper image interpretation and CT is preferred.

MRI can assist in identifying foreign body presence and complications in a variety of anatomical areas. Soft tissue objects can induce a chronic inflammatory reaction and lytic or blastic osseous changes that allow MRI to locate foreign bodies. In other cases, MRI is less optimal. Wood, especially if rich in water (as is the case with chronic foreign bodies), is better imaged with CT than MRI.

**Management**

The most important determinant of successful foreign body removal is knowledge of the object’s precise location. Standard radiopaque markers can aid in wound localization. Fluoroscopy or ultrasound may allow simultaneous visualization and removal. When objects are not radiopaque, judicious probing of wounds with fine-gauge needles or forceps may allow tactile detection of the foreign body. For metallic foreign bodies, magnets may facilitate removal.

For removal of a foreign body, it may be necessary to extend the original wound or, if it is located away from the entrance site, to make a separate incision. The emergency clinician can perform limited wound extension or make separate incisions in regions where adequate analgesia and a relatively bloodless field can be achieved. Retrieval of foreign bodies, especially those linear in shape, is best achieved if the orientation of the foreign body is understood. The proximal end of the foreign body is grasped, and the object is gently removed following the plane of orientation.

When inorganic objects are deeply embedded, it may be better to leave them in place than to create large surgical wounds to effect removal. Depending on foreign body location, operative intervention may be necessary for safe foreign body extraction. After foreign body removal, the emergency clinician should consider tetanus prophylaxis and empiric antibiotic treatment.

**Disposition**

Patients with suspected vascular or neurologic injuries require early evaluation by appropriate subspecialists. Soft tissue foreign bodies that are not suspected or undetected can lead to infectious sequelae. Therefore, careful discharge instructions and timely follow-up are crucial in these patients.
of the foreign body; (2) direct laryngoscopy with attempted manual removal with Magill forceps; or (3) cricothyroidotomy, other transtracheal ventilation, or intubation, while pushing the foreign body distally.

- Esophageal foreign bodies typically are found at one of the three constriction locations: (1) proximal esophagus at the level of the cricopharyngeal muscle and thoracic inlet—radiographically, the clavicular level; (2) midesophagus at the level of the aortic arch and carina; and (3) distal esophagus just proximal to the esophageal—gastric junction—radiographically, a level two to four vertebral bodies cephalad to the gastric bubble.

- Esophageal foreign bodies (eg, coins) usually are oriented in the coronal plane, and airway objects usually are oriented in the sagittal plane.

- Foreign bodies in the stomach and bowel are increasingly managed with a conservative approach with watchful waiting and tracking of the object’s progression through the gastrointestinal tract.

- In the perineal region, foreign body removal tends to be more difficult than anticipated by physicians and physically and psychologically traumatic for patients. Consultation with appropriate specialists (eg, urology or general surgery) is indicated.

- The most important determinant of successful soft tissue foreign body removal is an understanding of the object’s precise location.

The references for this chapter can be found online by accessing the accompanying Expert Consult website.

53.1. A 33-year-old construction worker presents with left eye pain. On gross inspection, you note a watery discharge and moderate erythema. The patient tells you she was working with her coworker when she felt something hit her eye. She admits to not wearing protective goggles. Fluorescein examination of the eye reveals rivulets of dye tracking from a corneal defect. What is the next appropriate step in the patient’s management?
A. Attempt ultrasound to find a foreign body
B. Check intraocular pressures
C. Obtain orbital computed tomography (CT) scan and consult ophthalmology
D. Obtain plain radiographs of the orbits
E. Topical antibiotics and ophthalmology follow-up in 24 hours

Answer: C. Rivulets of fluorescein tracking from the puncture (ie, positive Seidel test) are helpful in identifying the fact that intraocular penetration has occurred. Ultrasound is, as always, operator dependent, and the pressure of the probe on the orbit may risk further injury to an open globe. Checking for intraocular pressures with an open globe is contraindicated. Compared with plain radiographs, CT delivers less radiation to the lens. Multplanar reconstruction minimizes streak artifacts, affording better localization of intraorbital objects.

53.2. A 2-year-old presents with purulent drainage from the right naris, brought to the ED by a parent concerned about sinusitis. The patient’s vital signs are heart rate 110 beats/min, respiratory rate 15 breaths/min, and temperature 37.7°C. On physical examination, you see a small plastic ball in the naris surrounded by swelling and purulent discharge. What should be the next step?
A. Attempt to displace the foreign body posteriorly
B. Blow air into the contralateral naris to help dislodge the foreign body
C. Consult the otolaryngologist for removal under anesthesia
D. Make sure you have a right-angle probe, suction, and alligator forceps
E. Treatment with topical vasodilators to facilitate removal

Answer: D. The emergency clinician can remove most nasal foreign bodies. Posterior movement of a nasal foreign body risks aspiration; objects should be removed anteriorly via suction or traction. In some circumstances, it may be prudent to place patients in lateral decubitus, perhaps with additional Trendelenburg positioning, to help prevent aspiration of objects. Foreign bodies can sometimes be easily removed via positive pressure applied to the patient’s mouth (not the contralateral naris, which should instead be clamped closed to increase pressure on the involved-side naris). Pretreatment with vasoconstrictive spray may improve chances of success. If positive-pressure techniques are not indicated or do not work, it is important to have necessary instruments close at hand to proceed with foreign body removal attempts. These instruments include a blunt-tipped right-angle probe (to maneuver posterior to the foreign body), suction equipment, and alligator forceps.

53.3. A 14-month-old girl presents in respiratory distress after eating a hot dog for lunch. Her mother states that she had stepped out of the kitchen, and when she came back, her daughter was sitting forward with noisy breathing and obvious distress. Which of the following management interventions is contraindicated?
A. Back blows
B. Blind finger sweep as the first step
C. Chest thrusts
D. Direct laryngoscopic visualization
E. Intubate for respiratory distress

Answer: B. Blind finger sweeping has resulted in conversion of partial to complete airway obstruction when objects are displaced into the subglottic space. For this reason, the technique has lost favor as an initial maneuver in pediatric and adult patients. It is recommended that up to five back blows be delivered (with the patient in a head-down position), followed by chest thrusts. Intubation or needle cricothyroidotomy may be performed if other maneuvers fail and circumstances dictate their need.

53.4. A 45-year-old man was at dinner when he had a choking episode. When he recovered, he experienced new-onset wheezing and presents with the following vital signs: blood pressure 140/90 mm Hg, heart rate 110 beats/min, respiratory rate 20 breaths/min, and arterial oxygen saturation (SaO₂) 92%. On chest radiograph, you see a flat, fixed diaphragm on the right with a mediastinal shift to the left and inadequate left-sided expansion. What is the next step in the management of this patient?
A. Albuterol nebulizers and steroids intravenously
B. Consult pulmonary for bronchoscopy
C. CT scan of the chest with intravenous contrast
D. Needle decompression of the left side
E. Needle decompression of the right side

Answer: B. Air trapping and atelectasis are the most common early clues to airway foreign body presence, with bronchiectasis and bronchial stenosis developing later. In air trapping, a comparison of inspiratory and expiratory films shows a flat, fixed diaphragm on the involved side, and the heart and mediastinum shift to the uninvolved side during expiration. When the foreign object is distal to the oropharynx, however, subspecialty consultation is the safest and most expeditious means for foreign body removal. As a general rule, early bronchoscopy in any patient with a suspected foreign body is key to reducing morbidity and mortality.

53.5. A concerned father brings in his toddler, who has swallowed a button battery. Which of the following management strategies is most appropriate for this patient?
A. Endoscopy is indicated if it is above the lower esophageal sphincter.
B. Endoscopy is not indicated if it is found in the esophagus.
C. Expectant management is appropriate.
D. If it is in the small bowel, further surveillance is not indicated.
E. Nifedipine may aid in the movement of the battery through the esophagus.

Answer: A. If a disk battery has been ingested, its location must be ascertained with immediate removal if it has lodged in the esophagus. If the button battery has passed distal to the esophagus, the patient can be observed, with follow-up radiography to confirm spontaneous passage through the gastrointestinal tract. Nifedipine is occasionally effective in managing food boluses but should not be used to manage nonorganic foreign bodies.
53.6. Which of the following is an initial management option for esophageal food bolus impactions in the ED?
   A. Glucagon
   B. Nifedipine
   C. Papain
   D. Sublingual nitroglycerine

Answer: A. Two agents used for distal food bolus impaction, which are probably not as useful as glucagon, are nitroglycerine and nifedipine. A last approach, enzymatic degradation of an impacted meat bolus using the proteolytic enzyme papain, has fallen into disfavor because of risks of esophageal perforation. The gold standard intervention strategy for esophageal foreign body removal is endoscopy.

53.7. What do you expect to see on the chest radiograph of a child who has swallowed a coin?
   A. Foreign body anterior to tracheal air column
   B. Foreign body causing air trapping on the left side
   C. Visualized flat foreign body in the coronal plane
   D. Visualized round foreign body in the coronal plane
   E. Visualized round foreign body in the transverse plane

Answer: D. Esophageal foreign objects usually align themselves in the coronal plane and are posterior to the tracheal air column on lateral view. Coins in the esophagus lie in the coronal position in virtually all cases because the opening into the esophagus is much wider in this orientation.
CHAPTER 54

Mammalian Bites

Wesley P. Eilbert

PRINCIPLES

Background

It is estimated that 50% of individuals will suffer a domestic animal bite during their lifetime, with many of these bites being unreported.1 Dogs are responsible for over 80% of animal bites in the United States, with cats accounting for 5% to 10%. Although few studies exist that have examined the incidence of wild mammalian bites, rodents are probably the most common offender in this group. Bites from other species including monkeys, ferrets, raccoons, foxes, bears, cougars, bats, livestock, and other wild mammals make up only a small percentage of reported bites.

Bites cause damage to the skin and underlying structures including muscle, blood vessels, nerves, tendons, joint spaces, and bony structures. A secondary consideration with all bite wounds is contamination with the oral flora of the biting animal resulting in infection. The potential for tetanus and rabies exposure must also be considered. Tetanus is discussed in Chapter 52, and rabies in infection. The potential for tetanus and rabies exposure must also be considered. Tetanus is discussed in Chapter 52, and rabies is covered in Chapter 123.

DOG BITES

Principles

Of the nearly 4.5 million Americans bitten by dogs every year, half are children and one in five will require medical attention.2 Rates of dog bite are highest among children 5 to 9 years old, with males more likely to be bitten than females.3 The arm and hand is the body region most often bitten. Compared with adults, children are much more likely to be bitten on the face, head, or neck.4 In the majority of dog bite cases, the dog is known to the victim either as a family pet or a neighbor’s dog.4

Dog biting pressures exert forces of 200 to 400 pounds per square inch, and dogs often shake the victim vigorously. This causes a “hole and tear” effect resulting in complex lacerations and avulsions. On average, 10 to 20 dog bite related fatalities occur in the United States each year. The majority of victims are younger than 10 years old. Pit bulls and Rottweilers are the breeds responsible for the majority of these fatalities.5

Clinical Features

Dog bite wounds may be contusions or ecchymoses without a break in the skin, but more commonly are abrasions, lacerations, avulsions, or gaping crush wounds. Most dog bite injuries are superficial, and the majority of patients are treated with simple medication, dressings, or suturing. Larger breeds cause more severe crush injuries due to the higher pressures exerted by their jaws and pose a greater risk of major organ or vessel injury than smaller breeds. Dogs used in law enforcement exert greater bite forces than civilian dogs and are trained to use a bite-and-hold technique to apprehend suspected felons. These factors result in a higher overall incidence of bite complications including vascular, nerve and tendon injuries, fractures, and infections compared with bites from civilian dogs.

Dog bites to the hand are often of an occlusive nature, with the crush injury component increasing the risk of infection. Because of the several bones and joints adjacent to the skin surface, the number of small enclosed compartments and fascial planes, and numerous small nerves, hands are the most common bite site to develop infection and long-term morbidity.6 Tenosynovitis, septic arthritis, abscess formation, and traumatic digit amputation from dog bites have been reported.7

Dog bites to the head and neck are of cosmetic concern and are at greater risk of life-threatening injury. The lips, cheek, nose, and ears are the facial structures most likely to be bitten. Young children are at greatest risk for mortality from a dog bite, with exsanguination after carotid trauma as the major cause of death. In children up to 2 years old, there are case reports of dog bites that have perforated the skull, resulting in open depressed fractures, brain laceration, intracranial abscess, and meningitis.

Dog bites have reported infection rates ranging from 2% to 30%, with hand bites at higher risk for infection.8,9 Bites to the face and scalp are at lower risk for infection, presumably due to their rich blood supply. The type of wound appears to influence infection rates, with puncture wounds at higher risk for infection than avulsions and lacerations.8 Of infected dog bite wounds, 60% are punctures, 10% lacerations, and 30% a combination of these two. Thirty percent of dog bite infections are nonpurulent wounds, 58% are purulent, and 12% present as abscesses.

Dog bite wound infections are usually polymicrobial, with an average of five bacterial isolates per wound culture. The responsible bacteria are often a mixture of canine oral flora, environmental organisms, and the victim’s skin flora. Approximately half of dog bite–related infections contain a mixture of aerobic and anaerobic bacteria, with anaerobes more likely to be present in abscesses and purulent wounds. In contrast to older studies, more recent studies have found Pasteurella species to be the predominant organism, present in approximately half of infected dog bites. Other common aerobic bacteria include streptococci, staphylococci, Neisseria species, Corynebacterium species, and Moraxella species. Common anaerobic isolates from infected dog bites include Fusobacterium, Bacteroides, Porphyromonas, Prevotella, and Propionibacterium species.

Capnocytophaga Canimorsus

C. canimorsus was first identified in 1976 as a cause of systemic infection following dog bites. It is a slow-growing gram-negative rod found in the normal oral flora of both cats and dogs.10 C. canimorsus is a rare, though well-described cause of systemic illness. Transmission is related to a bite in the majority of cases, although has been documented from licks, scratches, or close animal contact.11 An animal is responsible for the infection in approximately 90% of cases, with 91% from dogs and 8% cats. In approximately 10% of cases, the source of infection is unknown. The disease tends to strike middle-aged men, with the majority of
affected individuals having underlying medical problems, most commonly alcoholism, splenectomy, or immunosuppression.1

The illness usually begins within 3 days of exposure (range 1 to 10 days). The most common initial symptom is fever, present in the majority of cases, followed by vomiting, diarrhea, abdominal pain, headache, and confusion. Cutaneous signs are common with purpuric lesions present in approximately one third of cases. These skin lesions may progress to peripheral gangrene in up to 15% of patients, with cutaneous gangrene at the site of the bite strongly suggestive of *C. canimorsus*. Although a minority of patients present with findings consistent with only cellulitis, the clinical picture on presentation is often that of sepsis with hypotension, renal insufficiency, respiratory distress, and disseminated intravascular coagulopathy (DIC). The few case series published have noted a mortality rate of approximately 30%. Endocarditis and meningitis from *C. canimorsus* has also been described.

**Differential Diagnoses**

The differential diagnosis of dog bites in general includes other domestic pets, such as cats and wild canines, including coyotes and wolves. The differential diagnosis for the patient with symptoms suggestive of *C. canimorsus* infection is extensive. Given its relative rarity and various initial symptoms, *C. canimorsus* infections are likely to be misdiagnosed and treated as other more common infections initially. Those patients with primarily cutaneous manifestations may be diagnosed with cellulitis or necrotizing fasciitis if systemic symptoms are also present. Invasive gastrointestinalitis would be an obvious consideration in those patients with primarily gastrointestinal symptoms, as would meningitis in patients presenting with fever, headache, and confusion. Bacteremia with another organism, especially *Neisseria meningitides*, should be considered in patients presenting with fever, hypotension, and purpuric skin lesions.

**Diagnostic Testing**

Radiographs should be obtained if there is a likelihood of damage to underlying bones and joints, such as with the hand. Bite penetration of joint capsules may be seen as air in the joint on plain radiographs. Scalp bites in children younger than 2 years old may require computed tomography (CT) imaging, because intracranial penetration and injury may occur.7 Premptive wound cultures sent from fresh bites are rarely of value and are not generally indicated.

*C. canimorsus* grows slowly and requires special media and growth conditions. In cases of sepsis without an obvious source following a dog or cat bite, *C. canimorsus* should be considered and the laboratory should be notified to arrange for appropriate testing. Polymerase chain reaction (PCR) has recently proven valuable in the rapid identification of *C. canimorsus.*11,13

**Management**

Key elements of the history can be divided into three main parts: (1) the circumstances of the attack, (2) information about the biting animal, and (3) information about the bite victim. The timing of the bite should be determined. As a general rule, untreated bites more than 6 hours old are at higher risk for infectious complications. When possible, it should be determined whether the bite was provoked or unprovoked, because this may influence the decision to administer rabies prophylaxis. Information about the biting animal should include ownership and immunization status, as well as current location of the animal. With dog bites, inquiring about the specific breed is important, because certain breeds (eg, German shepherds, Rottweilers, and pit bulls) notoriously cause severe bites with damage to underlying structures. Information about the bite victim should include their medical history, current medications, and tetanus status.

The general principles of wound management apply to bite wound patients (see Chapter 52). Adequate analgesia is vital to allow for appropriate examination and wound care. Washing the wound with soap and water, ideally with gentle scrubbing with a fine pore sponge to minimize additional tissue trauma, should be performed. A virucidal agent such as povidone-iodine solution should be used, specifically if there is a concern for rabies exposure.

Examination of bite wounds should ideally take place in a bloodless field to allow for adequate visualization of deep structures. A blood pressure cuff inflated above the systolic pressure for up to 20 minutes can be used for this purpose. The wound should be examined specifically for damage to tendons and possible joint capsule violations. Any retained teeth fragments should be removed. It is often helpful to extend the margins of puncture wounds in high risk areas (eg, overlying joints and tendons) to allow for better visualization. Assessment of the neurovascular status distal to all extremity bites should be performed. As with other traumatic wounds, appropriate high pressure irrigation with normal saline or sterile water and débridement of devitalized tissue is necessary.

Primary closure of mammalian bites is controversial with conflicting data having been reported. Ultimately, the benefit of improved cosmesis of primary closure must be weighed against the increased risk of infection. Studies have found no significant difference in rates of infection between repaired dog bite wounds and those left open. Carefully selected dog, cat, and human bites closed primarily have an overall infection rate of 5.5%, which is an infection rate similar to sutured non-bite wounds. When closing bite wounds, the use of subcutaneous sutures should be kept to a minimum, because the presence of foreign material increases the risk of infection. To optimize cosmetic outcome in those wounds deemed too high risk for infection for primary closure, loosely approximating the wound edges using adhesive strips may be performed. Another option is to reevaluate the wound in 48 to 72 hours and if no evidence of infection is present, perform a delayed primary closure.

Given the available data, we recommend the following guidelines (Table 54.1). Bite wounds of the face and scalp from any

species that are less than 6 hours old may be sutured after appropriate wound preparation. It is probably safe to suture most other uncomplicated dog bites. Bites of the hands and feet are at high risk for infection and should rarely be sutured. Puncture wounds, wounds more than 12 hours old, and wounds infected at presentation should not be sutured. Prophylactic antibiotic should be given for the majority of bite wounds closed primarily.

Prophylactic Antibiotics

The value of prophylactic antibiotics given for mammalian bites is secondary to the value of proper cleaning, débridement, and irrigation of the wounds. Antibiotics should ideally be given within 3 hours of the bite to achieve a prophylactic effect and then continued for 3 to 5 days. A Cochrane review including eight randomized controlled trials of prophylactic antibiotics for dog, cat, and human bites concluded that antibiotics did not reduce infection risk after dog and cat bites.8 The analysis also established that the type of wound (eg, laceration versus puncture) did not appear to influence the effectiveness of the prophylactic antibiotic. Sub-analysis of hand bites showed infection rates were significantly reduced by antibiotics.9

A meta-analysis of eight published studies using prophylactic antibiotics for dog bites estimated approximately 14 patients would have to be treated to prevent one infection.10 A sub-analysis of the data found a protective effect specifically with hand bites. A recent study of prophylactic antibiotics after dog bites with cost model analysis of treatment suggested treating only those dog bites at high risk for infection.11 We advise giving prophylactic antibiotics to high-risk patients and to those with dog bite wounds of the hand or other high risk wounds (Table 54.2).

No clinical trials have reliably demonstrated the superiority of one antibiotic regimen over another. With a significant percentage of dog bite infections caused by Pasteurella species, coverage of these pathogens is recommended. Treatment failure of Pasteurella infections caused by dog and cat bites using monotherapy with erythromycin, clindamycin, penicillinase-resistant penicillins, and first-generation cephalosporins has been described. We recommend amoxicillin-clavulanate (Augmentin) for dog bite prophylaxis because this combination is active against most of the pathogens that can be isolated from these wounds in vitro, and studies have demonstrated it is effective in vivo.12 Clindamycin combined with either trimethoprim-sulfamethoxazole or ciprofloxacin may be used in penicillin-allergic patients (Table 54.3). Empirical antibiotic options for those patients with established dog bite wound infections are the same as those used for prophylaxis. Parenteral antibiotic options for those patients requiring admission are listed in Table 54.3.

Although no clinical trials have evaluated antibiotic selection in C. canimorsus infections, penicillin G, ampicillin-sulbactam, third-generation cephalosporins, and fluoroquinolones have all been effective for in vitro studies.

Disposition

Indications for admission after an animal bite are listed in Box 54.1. Those patients deemed appropriate for outpatient therapy should be reevaluated in 24 to 48 hours.

Indications for Admission After an Animal Bite

**STRUCTURAL**
- Injury to deep structures (bones, joints, tendons, arteries, or nerves)
- Injuries requiring reconstructive surgery
- Injuries requiring general anesthesia for appropriate wound care

**INFECTIOUS**
- Rapidly spreading cellulitis
- Significant lymphangitis or lymphadenitis
- Evidence of sepsis
- Infection in patients at high risk for complications (see Table 54.2)
- Infections involving bones, joints, tendons
- Infection with failed outpatient therapy

**CAT BITES**

**Principles**

Although victims of dog bites are more likely to be male, females are twice as likely as males to be the victim of a cat bite, with a peak age incidence in the third decade. The majority of cat bites are to the upper extremity, particularly the hands and fingers. The risk of infection after cat bites is the presence of cat scratches, dog bites, or open wounds that have been licked by a dog or cat. More than 80% of cat bites are caused by a domestic pet that is owned by the victim. Cats possess narrow sharp teeth that easily penetrate skin and the underlying soft tissues like a needle. This mechanism creates a small break in the skin that heals quickly, trapping the bacteria in the deeper structures, often resulting in invasive infection.

**Clinical Features**

Cat bites are more likely to become infected than dog bites, with reported infection rates of up to 80%. This increased rate of infection is multifactorial: The higher incidence of puncture wounds, a higher proportion of hand bites, an older average age for cat bite victims, and a higher likelihood of Pasteurella species in the feline flora. Although not as likely to cause damage by crush injury as dog bites, cat bites are more likely to cause infection in deeper structures, including osteomyelitis and soft tissue abscesses. Of infected cat bite wounds, 52% present with cellulitis, 22% with tenosynovitis, 15% with osteomyelitis or septic arthritis, and 11% with an abscess.

**Bacteriology**

There is a median of five bacterial isolates per culture of infected cat bites, with mixed aerobic and anaerobic bacteria present in 63%. Thirty-two percent of cat bite infections are due to only aerobic pathogens. Pasteurella species are the most common pathogens, present in 70% to 75% of infected cat bites, with streptococci, staphylococci, Moraxella, and Bacteroides also common aerobic pathogens. Common anaerobes include Bacteroides, Fusobacterium, Porphyromonas, and Prevotella.

**Pasteurella Multocida.** An important factor contributing to the risk of infection after cat bites is the presence of *P. multocida*, a highly virulent, facultative anaerobic, gram-negative rod found in the normal oral flora of up to 90% of cats. It can also be found in the oral flora of the majority of dogs and several wild animals. Most human infections with *P. multocida* are caused by cat bites or scratches, dog bites, or open wounds that have been licked by a dog or cat.

The most common initial manifestation of *P. multocida* infection is a rapidly spreading cellulitis, usually presenting within 12 to 24 hours of the exposure. A low-grade fever and serosanguineous or purulent discharge at the site may be present. Regional lymphadenopathy is often present. Left untreated, local complications, most commonly subcutaneous abscesses and tenosynovitis, may occur. Other local complications include septic arthritis and osteomyelitis. Systemic illnesses from *P. multocida* including bacteremia, pneumonia, endocarditis, and meningitis have been well described in case series. The majority of patients with systemic illness had an underlying medical condition, with liver disease, malignancy, and chronic obstructive pulmonary disease being the most frequent comorbidities. There is a 31% mortality rate from *P. multocida* bacteremia.

**Differential Diagnoses**

The cellulitis associated with *P. multocida* is typically of more rapid onset after the initial traumatic injury and more rapidly progressive than the cellulitides caused by more common pathogens. Cat scratch disease, an infection caused by *Bartonella henselae* associated with a cat scratch or bite, presents with a regional lymphadenopathy often with an associated fever. A preceding cat or dog bite may be the only initial clue that indicates *P. multocida* as the cause of a systemic illness, such as bacteremia.

**Diagnostic Testing**

As with dog bites, radiographs should be obtained if there is a likelihood of damage to underlying bones and joints, such as with the hand. Bite penetration of joint capsules may be seen as air in the joint on plain radiographs. Preemptive wound cultures sent from fresh bites are rarely of value and are not generally indicated.

**Management**

*P. multocida* is not susceptible to many oral antibiotics typically given for skin and soft tissue infections, including dicloxacillin, cephalaxin, and clindamycin. In most cases, treatment with a beta-lactam antibiotic (such as, ampicillin), amoxicillin-clavulanate, or a second or third generation cephalosporin is effective. Fluoroquinolones, tetracyclines, and trimethoprim sulfamethoxazole may be used in penicillin allergic patients.

There is only one published randomized controlled study of prophylactic antibiotics in cat bites; although small, it demonstrated reduced infection. A Cochrane review concluded there was no evidence that antibiotic prophylaxis was effective for cat bites, although the authors also concluded that animal bites on the hands (where most cat bites occur) benefit from prophylaxis.

We advise giving prophylactic antibiotics to all cat bites that penetrate through the epidermis regardless of location, given the high risk nature of these bites for infection. With similar common pathogens as dog bites, we recommend amoxicillin-clavulanate (Augmentin) be used for prophylaxis (see Table 54.3).

**Disposition**

Indications for admission after an animal bite are listed in Box 54.1. Those patients deemed appropriate for outpatient therapy should be reevaluated in 24 to 48 hours.

**OTHER MAMMALS**

**Monkeys**

**Principles**

Monkey bites are rare in the United States, occurring primarily in laboratory workers because these animals are widely used in...
biomedical research. Monkey bites are more prevalent in other countries including India, where they are the second most commonly reported animal bite. Although not well studied, monkey bites are reported to have a high rate of infection and complications, such as osteomyelitis.

Clinical Features
The major concern with monkey bites is B virus exposure. Other terms for this virus include herpesvirus simiae, herpesvirus B, and monkey B virus. This virus has serologic cross-reactivity with herpes simplex virus (HSV) type 1 and type 2, which cause herpetic lesions in humans. Seventy-three percent to 100% of monkeys of the genus Macaca (macaques) used for biomedical research are seropositive for the B virus. The virus causes disease in monkeys resembling that of human herpes viruses. Asymptomatic infected monkeys harbor the virus in their conjunctiva, buccal mucosa, and genital areas and may shed the virus, being more likely to do so when ill, under stress, immunocompromised, or breeding.

More than 50 cases of B virus infection in humans have been reported, with the vast majority of these in the United States being in laboratory workers. Of those investigated, the majority were due to monkey bites, although transmission via scratches, exposure to animal tissue, and needlestick injuries has been reported. B virus disease in humans has an incubation period as short as 2 days but more commonly 2 to 5 weeks. The disease often starts with vesicular lesions at the site of exposure with concomitant influenza-like symptoms. Paresthesias and muscle weakness may develop and proceed proximally along the affected extremity. Signs of central nervous system dysfunction develop when the virus enters the brain and include altered mental status, cranial nerve palsies, ataxia, coma, and respiratory failure. Left untreated, the mortality rate of B virus infection is estimated to be 80%.

Differential Diagnoses
The bacteria isolated from infected monkey bites is similar to that from infected human bites, with a predominance of Staphylococcus and Streptococcus species, Eikenella corrodens, and anaerobes including Bacteroides and Fusobacterium species.

Management
The most critical period for the prevention of B virus infection is during the first few minutes after the exposure. The area should be scrubbed with soap, concentrated solution of detergent, povidone-iodine or chlorhexidine, and then irrigated with running water for 15 to 20 minutes.22 Prophylaxis of high risk bites with valacyclovir is recommended (Box 54.2). Postexposure prophylaxis should be offered for up to 5 days after the bite, although it should be started as soon as possible. Treatment of suspected B virus infection is with intravenous acyclovir or ganciclovir.

Disposition
The majority of monkey bites can be safely discharged home from the emergency department (ED) following local wound care, appropriate antibiotics, and reassurance of outpatient follow-up. Those patients with systemic symptoms of infection may require admission for intravenous antibiotics.

Rodents
Principles
As with monkey bites, laboratory workers are frequent rodent bite victims because these animals are commonly used in biomedical research. Rat bites tend to occur in urban areas, in patients of low socioeconomic class, and are more common in children. The majority of these bites occur while the victim is asleep, with the face and upper extremity being the areas most often bitten.

Clinical Features
Rat bite fever is a disease syndrome caused by Streptobacillus moniliformis or Spirillum minus, both found in the nasopharyngeal flora of healthy rats. Over 200 cases of rat bite fever have been documented in the United States, but this is likely a significant underrepresentation because rat bite fever is not a reportable public health disease.22 Disease transmission may occur by bite, scratch, or simply handling a rat.22 The incubation period ranges from 3 days to over 3 weeks but typically is less than 7 days. At disease onset, fever is prominent, followed by a migratory polyarthralgia. Nearly 75% of patients develop a maculopapular, petechial, or purpuric rash. Untreated, rat bite fever has a mortality rate of approximately 10%.

Differential Diagnoses
A number of systemic diseases may be transmitted by rodent bites including rat bite fever, leptospirosis, tularemia, sporotrichosis, murine typhus, and plague.

Management
Rodent bites are at low risk for local wound infection and require only appropriate wound care without antibiotic prophylaxis.

---

**BOX 54.2**

**Prophylaxis for Monkey Virus B Exposure**

**PROPHYLAXIS RECOMMENDED**
Skin exposure (with loss of skin integrity) or mucosal exposure to a high-risk source (eg, a macaque that is ill, immunocompromised, known to be shedding virus, or has lesions compatible with B virus disease)
Inadequately cleaned skin exposure (with loss of skin integrity) or mucosal exposure to any macaque
Deep puncture bite
Laceration of the head, neck, or torso
Needlestick associated with tissue or fluid from the nervous system, eyelids, mucosa, or lesions suspicious for B virus
Puncture or laceration after exposure to objects contaminated with either fluid from monkey oral, genital, or nervous system tissues or any object known to be contaminated with B virus
A post cleaning wound culture is positive for B virus

**PROPHYLAXIS CONSIDERED**
Mucosal splash that has been adequately cleaned
Laceration (with loss of skin integrity) that has been adequately cleaned
Needlestick involving blood from an ill or immunocompromised macaque
Puncture or laceration occurring after exposure to either objects contaminated with body fluid (other than from a lesion) or potentially infected cell culture
Drug of first choice: Valacyclovir 1 g by mouth every 8 hours for 14 days
Alternative drug: Acyclovir 800 mg by mouth five times/day for 14 days

**PROPHYLAXIS NOT RECOMMENDED**
Skin exposure in which the skin remains intact
Exposure associated with non-macaque species of nonhuman primates
Intravenous penicillin is the treatment of choice for proven or highly suspected cases of rat bite fever, with streptomycin and tetracycline reasonable options for penicillin allergic patients. Antibiotic prophylaxis for rat bite fever is not recommended given the low risk for infection after a bite.

Disposition

The vast majority of rodent bites can be safely discharged home from the ED with wound care instructions and outpatient follow-up.

Ferrets

Ferrets (*Mustela putorius furo*) are in the same family as badgers, weasels, and skunks, and became increasingly popular as pets in the United States in the 1980s. Initially bred to hunt rats and rabbits, ferrets are known for their exceptionally vicious attacks, with infants and small children often being their victims. Unlike dog and cat bites, many ferret bites are unprovoked and will frequently require plastic and reconstructive surgery. Although the oral flora of ferrets is known to contain *Pasteurella* and other aerobic species and *Fusobacterium* and other anaerobic species, no reports exist that have examined the rates of infection or common pathogens with ferret bites.

DOMESTIC HERBIVORES

Sheep, Cattle, and Pigs

Bites from sheep and cattle are rarely reported in the medical literature. Pig bites are a common occupational hazard among farmers and slaughterhouse workers and most commonly occur on the posterior aspect of the thigh. Males have large, sharp tusks capable of deep penetrating wounds with injury to deeper structures. Bites from females are less damaging. Pig bites have a high incidence of infection that is often polymicrobial with organisms including *Staphylococcus* and *Streptococcus* species, *Hemophilus influenzae*, *Pasteurella*, *Actinobacillus*, and *Flavobacterium* species.

Horses

Of all horse-related injuries, most are from falls and less than 5% are due to bites. Horse bite injuries range from superficial trauma to amputation of digits. Horse bite infections are typically polymicrobial with a mix of aerobic and anaerobic species. *Actinobacillus* species are gram-negative coccobacilli that are part of the normal oral flora of horses and common pathogens in infected bites. Other common pathogens include *Staphylococcus* and *Streptococcus* species, *Pasteurella* species, as well as *Fusobacterium* and *Bacteroides* species.

Camels

Camel bites are commonly reported in Africa, the Middle East, and the Indian subcontinent. Camel bites are more likely to occur during their mating season from November through March, with most injuries occurring to the upper extremities. Camel have a strong jaw and canine teeth that may reach up to 4 cm in length, which result in serious injury and even death from their bites. A recent study found 48% of upper extremity bites had associated fractures, and bites to the head have been associated with skull fractures and intracranial injury. Camel bites have a high infection rate with *Staphylococcus aureus*, *Streptococcus pyogenes*, *Pseudomonas aeruginosa*, and *Bacteroides* and *Fusobacterium* species as common pathogens.

WILD ANIMALS

Bears

Bear attacks are rare in North America, occurring at a rate of 10 or fewer per year, with most occurring in the western United States and Canada. Bear attacks are more common in the warm weather months and have a reported mortality rate of up to 21%. Grizzly bears are responsible for an inordinate number of serious and fatal injuries caused by bears in North America. Most bear bites are to the head and face, often with underlying bony injury. Although not well studied, bear bites have a reported infection rate of 44%. The bacteriology of bear bite infections has also not been well described.

Wild Cats

Most attacks by big cats (lions, tigers, leopards, jaguars, cougars, and cheetahs) now occur in captive conditions, such as zoos, animal farms, and circuses, although attacks in the wild are still reported with some frequency in Asia and Africa. Large cats target the neck of their prey, causing damage to the spine, trachea, and large blood vessels. Cougars are responsible for the majority of big cat attacks in North America, with children the most common victims and the nape of the neck being the most commonly bitten area. Common injuries from these attacks include neck lacerations and internal carotid and cervical spine injuries. As is true for domestic cats, *Pasteurella multocida* is the most frequently isolated pathogen in wounds from large cats. Hyenas, which are related to cats, have been known to attack humans in the wild in Africa and Asia. Unlike the big cats, hyenas tend to bite the central face of their victims, causing damage to the cheeks, nose, and lips.

Coyotes and Wolves

Bites from coyotes and wolves are similar to dog bites and should be treated as such.

Management

As with non-bite lacerations, location, type of wound, time to treatment, and patient factors all contribute to the risk of wound infection. Delay in wound cleaning and inappropriate cleaning techniques will increase infection risk. The animal responsible for the bite also is a factor in determining the risk of infection (see Table 54.2).

Although there are no studies to support the practice, antimicrobial prophylaxis for bites from other mammals is often provided. Ferrets, pigs, horses, bears, big cats, coyotes, and wolves have bite wound pathogens similar to those of dogs and cats, so in the absence of other data, prophylactic antibiotics given for these bites should also be similar. A unique mixture of camel bite wound pathogens is most adequately covered by fluoroquinolone antibiotics (see Table 54.3).

Other Prophylaxis

Tetanus prophylaxis should be considered for all bite wounds. Rabies immunization should be considered following bites from bats, coyotes, foxes, raccoons, skunks, and stray dogs outside of the United States.

Disposition

Indications for admission after an animal bite are listed in Box 54.1. Those patients deemed appropriate for outpatient therapy should be reevaluated in 24 to 48 hours.
**PART II**

Intraoral and oral-cutaneous wounds caused by the patient's own teeth are usually a result of blunt facial trauma. These bite wounds are typically small and confined to the oral mucosa, requiring no specific intervention. Larger wounds of the mucosa and those that communicate with the overlying facial skin (“through and through” wounds) may require closure for functional or cosmetic reasons. Infection rates of these wounds range from 4% to 33%. Organisms cultured from these infected wounds include *Staphylococcus* and *Streptococcus* species, *Bacteroides* and *Corynebacterium*. In the absence of any current clear evidence-based recommendation regarding the use of prophylactic antibiotics for these wounds, we advise prophylactic penicillin be used in those lacerations requiring primary closure and those that result in mucocutaneous communication.

**Bacteriology.** Human saliva can contain up to $10^8$ organisms per mL, and may contain as many as 190 different species of bacteria. As with other mammalian bites, cultures sent from fresh, uninfected human bite wounds do not predict which patients will become infected, nor do they reveal the responsible pathogens in those who do. Information on the bacteriology of infected human bite wounds has come primarily from hand bites, with the majority being CFIs. Polymicrobial infections are the rule with human bites, with an average of four isolates per wound culture. Approximately half contain a mixture of aerobic and anaerobic species, with less than 5% containing only anaerobes. *Staphylococcus* and *Streptococcus* species, as well as *Corynebacterium* and *Fusobacterium* species, are common pathogens. *Eikenella corrodens*, a fastidious facultative anaerobe, is present in up to 30% of infected human bites. It is resistant to multiple antibiotics including clindamycin, erythromycin, antistaphylococcal penicillins, and first-generation cephalosporins.

**Differential Diagnoses**

Human bites have resulted in transmission of tetanus, syphilis, actinomycosis, and herpes. Herpetic whitlow, an infection of the finger by HSV types 1 and 2, is an occupational hazard of nurses, physicians, dentists, and oral hygienists (Fig. 54.2). Although the presence of human immunodeficiency virus (HIV) inhibitors in saliva render the virus non-infective in most cases, there are

---

**Principles**

Males are more likely to be the victims of human bites, with a peak incidence in the 10- to 34-year-old age group. Human bites tend to occur during summer months, typically on weekends, and most often involve acts of aggression. Sporting events and rough sexual activity are less common causes. The hands and upper extremities are the most commonly bitten location, followed by the head and neck. With victims of sexual crimes, the breast is the most commonly bitten area, and the arm is the most frequently bitten site in victims of child abuse. For various reasons, including embarrassing circumstances and possible legal repercussions, many adult human bite victims delay seeking medical care until a complication ensues. This is especially true for human bites of the hand.

Human bites can be divided into two categories: occlusive bites and clenched fist injuries (CFIs). Occlusive bites are those caused by closure of the perpetrator’s teeth onto the victim’s skin. CFIs, or “fight bites,” are injuries to the dorsum of the metacarpophalangeal joints of the fist as it strikes the teeth of an adversary. The overwhelming majority of CFIs occur in young adult males and frequently involve alcohol. Human bites have reported infection rates ranging from 2% to 50%, with hand bites and specifically CFIs having the highest rates of infection. Children, in whom human bites are usually superficial, tend to have lower rates of infection (less than 10%) as compared with adults.

**Clinical Features**

**Fight Bites (Clenched Fist Injury)**

Acute CFIs typically present as an innocuous-appearing 3 to 8 mm laceration over the dorsal aspect of the second, third, fourth, or fifth metacarpophalangeal (MCP) joint (Fig. 54.1). Despite their initial benign appearance, CFIs often have extensive deep structure damage. Damage to underlying bones occurs in approximately half CFIs, and approximately half will have violation of a joint capsule. Up to 20% of CFIs will have an associated tendon injury. Injury to the extensor tendons occurs with the fist clenched. When the fist is relaxed, the tendons retract, carrying bacteria deeper into the hand, extending infection to other spaces. Retained teeth or tooth fragments in the wound may also occur. Given these facts, it is not surprising that CFIs have high rates of osteomyelitis (16%), septic arthritis (12%), and tenosynovitis (22%). Further confounding this issue is the fact that many patients will be reticent to discuss the details of their injury, and approximately one third of CFI patients will initially offer an alternative explanation for their hand laceration.

**Fig. 54.1.** Acute clenched fist injury (CFI). (Courtesy Jeffrey E. Keller, MD.)

**Other Human Bites**

Human occlusive bites generally cause less tearing and crush injury than dog bites, and do not penetrate soft tissues as readily as cat bites. Occlusive human bites that are superficial, do not involve the hands or feet, and are not over joints or cartilaginous structures have a very low rate of infection and do not benefit from prophylactic antibiotics.

**Fig. 54.2.** Herpetic whitlow. (Courtesy Gary M. White, MD.)
several case reports of HIV transmission by human bites. Several people have become infected with hepatitis B virus (HBV) from human bites, and the risk of HBV transmission from a bite appears greater than that of HIV. The infectivity of the hepatitis C virus (HCV) from a bite is believed to be midway between that of HIV and HBV, and there are case reports of its transmission by human bites.

**Diagnostic Testing**

Due to their high incidence of deep structure injury and the possibility of retained tooth fragments, we advise obtaining radiographs in the majority of hand bites. A "skyline" view of the distal metacarpals may aid in the identification of vertical articular fractures of the metacarpal heads caused by CFIs.

**Management**

History should focus on the mechanism of the bite (occlusive or CFI), the health of the bite victim including medical history and tetanus status, and the potential for transmission of viral hepatitis or HIV. If the biter is available for testing, local law may permit testing even without consent depending on the particular circumstances.

Treatment of occlusive human bites is generally similar to that of other mammalian bites. Although some authors have advocated surgical exploration of all CFIs in the operating room, we recommend nonoperative management in the ED for selected patients. Such an approach is predicated on thorough wound exploration in a bloodless field. The hand should be examined through its entire range of motion, including in the closed fist position when the fingers are flexed, because extensor tendon injuries and cartilage damage may not be evident in any other position. Patients in whom exploration shows injury to the joint or joint capsule, tendons, or bones should be admitted for open débridement and irrigation in the operating room. It is typical for patients with CFIs to present several days after the injury with evidence of an infected wound. These patients will also require surgical exploration and irrigation in the operating room.

Given their propensity for infection, only human bites to the face should be closed primarily. Case series of human facial bites closed primarily have reported infection rates of 0% to 10%, although all of these studies reported delays of treatment of up to several days. We recommend primary closure of human bites to the face be performed up to 24 hours after the bite has occurred (see Table 54.1). Those CFIs not requiring operative intervention should be cleaned, debrided, and irrigated, then left open with the hand splinted in a position of comfort.

HIV postexposure prophylaxis is recommended for both the bite victim and the bite source if either party is known to be HIV-positive or at high risk and blood exposure has occurred. Postexposure prophylaxis is also indicated in all bites if either party is known to be HBV-positive or at high risk and blood or saliva exposure has occurred. No current postexposure prophylaxis is available for HCV, so serologic testing with appropriate follow-up and counseling should be offered if the bite resulted in blood exposure, and either party is known HCV positive or at high risk.

**Prophylactic Antibiotics**

The only randomized, placebo-controlled study of patients with human bites found no infections in patients who received timely antibiotics, and a 47% infection rate in those patients that received placebo. Of significance is that this study only included hand bites. A Cochrane review concluded that prophylactic antibiotics do reduce infection risk after human bites. We advise the use of prophylactic antibiotics for any human bite that penetrates deeper than the epidermis regardless of body location, with the exception of those bites greater than 72 hours old without evidence of infection. We recommend beta-lactam-beta-lactamase inhibitor combination antibiotics, such as amoxicillin-clavulanate (Augmentin), or fluoroquinolones with enhanced anaerobic activity, such as moxifloxacin, for human bite prophylaxis. Other prophylactic antibiotic options are listed in Table 54.3. As with other prophylactic antibiotics, the first dose should be given ideally within 3 hours of the injury and continued for 5 days.

**Disposition**

Delay in presentation with human bites to the hand is strongly correlated with infection related complications, and these patients should be admitted for parenteral antibiotics. Other indications for admission with human bites of the hand are listed in Box 54.3. Localized infections of human bites elsewhere on the body in immunocompetent patients can usually be treated as an outpatient. All patients with human bites discharged from the ED should have their wounds reevaluated in 24 to 48 hours. Patients with CFIs have notoriously high rates of noncompliance with follow-up care. It is reasonable to admit patients who might predictably fall into this category.

**KEY CONCEPTS**

- Mammalian bites require evaluation not only as traumatic injuries but also for their risk of infection.
- Cat and human bites are at higher risk for infection than dog bites.
- Most mammalian bite wound infections are polymicrobial.
- *Pasteurella* species are the most common pathogens in dog and cat bites.
- The value of prophylactic antibiotics for mammalian bites is secondary to the value of proper cleaning, débridement, and irrigation of the wounds.
- Prophylactic antibiotics should ideally be given within 3 hours of the bite and continued for 5 days.
- Amoxicillin-clavulanate (Augmentin) is the prophylactic antibiotic of choice for dog, cat, and human bites. Moxifloxacin is an alternative for those patients that are penicillin-allergic.
- The decision to close mammalian bite wounds must weigh the benefit of improved cosmesis against the increased risk of wound infection.
- Given their propensity for infection, mammalian bites to the hand should not be closed primarily. Most facial bites can safely be closed if done so within 24 hours of the bite.
- Due to the anatomy of the hand, clenched fist injuries (CFIs) or “fight bites” have exceptionally high rates of damage to deep structures and infection.
- Mammalian bites to the hand should receive prophylactic antibiotics. Any infected human bite to the hand should be treated on an inpatient basis.

The references for this chapter can be found online by accessing the accompanying Expert Consult website.
54.1. A 75-year-old woman presents with a puncture mark on her hand. She reports being bitten by her cat the previous night. Which of the following statements regarding this patient’s injury is true? 

A. **Capnocytophaga canimorsus** is the organism of concern. 
B. Cats are very clean animals and do not carry any virulent strains. 
C. Cats produce superficial infections because their teeth are not long enough to inoculate past the dermis. 
D. Concern exists for a virulent gram-negative bacterium, which can produce a rapid cellulitis. 
E. Irrigation and topical antibiotics are indicated.

**Answer:** D. Cats have long, slender, pointed teeth that can penetrate tendons, joints, and bone, inoculating bacteria deep into these tissues. Cat bites have a substantially higher risk of infection than dog bites do. Another important factor in the development of wound infection after cat bites involves the presence of Pasteurella multocida, a highly virulent, gram-negative, facultatively anaerobic rod found in the oral cavity or nasopharynx of 70% to 90% of healthy cats.

54.2. What is the most appropriate antibiotic prophylaxis for a cat bite? 

A. Amg: amoxicillin-clavulanate 
B. Clindamycin 
C. Erythromycin 
D. First-generation cephalosporins 
E. Vancomycin

**Answer:** A. In vitro, *P. multocida* is sensitive to penicillin, ampicillin, tetracycline, fluoroquinolones, amoxicillin-clavulanate, second- and third-generation cephalosporins, and trimethoprim-sulfamethoxazole.

54.3. A 19-year-old man presents 10 hours after sustaining a dog attack. He has multiple lacerations on his head and right hand. What is the appropriate management of this patient? 

A. Repair the hand and the head lacerations 
B. Repair the head laceration but not the head laceration 
C. Repair the head laceration but not the hand laceration 
D. Use Steri-Strips on all and give him a prescription for amoxicillin-clavulanate (Augmentin) 
E. Wound cleansing and bandaging

**Answer:** C. For dog bites, the infection rate of hand wounds is as high as 30%, regardless of suturing, whereas the infection rate of dog bites elsewhere averages 9%. Similarly, dog bites of the face and neck (including punctures) have an infection rate of only 0% to 5% even when they are sutured. Bite wounds of the face and scalp from any species that are less than 12 hours old may be cleaned well and sutured. Most other bite wounds that are going to be closed should have this done within 6 hours.

54.4. Selected monkey bites require postexposure prophylaxis with which of the following medications? 

A. Amoxicillin clavulanate 
B. Clindamycin 
C. Flagyl 
D. Tetracycline 
E. Valacyclovir

**Answer:** B. Clindamycin

Answer: E. Valacyclovir to prevent herpes B virus infection. Other terms for this virus include *herpesvirus simiae*, *herpesvirus B*, and *monkey B virus*. This virus has serologic cross-reactivity with herpes simplex virus (HSV) type 1 and type 2, which cause herpetic lesions in humans. Seventy-three percent to 100% of monkeys of the genus *Macaca* (macaques) used for biomedical research are seropositive for the B virus. Other antibacterials may be needed if cellulitis infection ensues.
Venomous Animal Injuries

**CHAPTER 55**

### PRINCIPLES

#### Epidemiology

Venomous animals account for considerable morbidity and mortality worldwide. Southeast Asia, India, Brazil, and areas of Africa lead the world in snakebite mortality. Snakes alone are estimated to inflict 2.5 million venomous bites annually, with approximately 125,000 deaths. It is impossible to estimate the worldwide morbidity and mortality resulting from other venomous animals, such as bees, wasps, ants, and spiders.

Approximately 45,000 snakebites occur annually in the United States; 7000 to 8000 are inflicted by venomous snakes, and fewer than 10 result in death. Insects are responsible for 52% of deaths, snakes for 30%, and spiders for 13%. Specifically, bees are responsible for the most fatalities, followed by rattlesnakes, wasps, and spiders.

The American Association of Poison Control Centers began collecting data in 1983 on deaths caused by venomous animals. Their 30-year experience shows a significant number of exposures by bite or sting but relatively few deaths (Table 55-1). Although these data include most of the United States, there is no requirement that hospitals, emergency departments (EDs), coroners, or public health agencies report deaths or exposures to regional drug and poison information centers. This decline in deaths may be caused by an actual decrease in mortality or may be a result of inadequate reporting. Meaningful morbidity data, such as the number of amputations, hospitalizations, and disabilities, do not exist. The number of exposures and deaths from nonnative snakes seems to be increasing, possibly because of interest in collecting “exotic” or venomous varieties, such as cobras, mambas, and vipers. The morbidity from marine animal injuries is increasing in proportion to the number of people exposed to the ocean and the number of private collectors, but the mortality has not increased dramatically. An increase in outdoor recreational activities, such as camping, scuba diving, wilderness trekking, and travel to endemic areas puts more people in proximity to venomous animals and increases the risk of envenomation. Most exposures occur from April to October, which is when animals are most active and potential victims are outdoors and involved in activities that might increase their risk for envenomation. Many snake bites and exotic animal envenomations that occur indoors can take place at any time. Most deaths seem to occur in very young, elderly, or inappropriately treated patients.

#### Venom Delivery

Animals that have developed specific venom glands and venom delivery systems can be found in every class, including birds. The toxin and toxic apparatus vary from class to class. For example, the rattlesnake has modified salivary glands and maxillary teeth and uses this system primarily to obtain food. The bee has a modified ovipositor that is used mainly for defense. Poisonous and venomous animals are not the same and should be differentiated. Animals can be considered poisonous because of various toxins distributed in their tissues. For example, certain shellfish, toads, and barracuda have been known to cause death after ingestion. However, only animals with specific glands for producing venom connected to an apparatus for delivering that venom to another animal can be considered venomous.

### VENOMOUS REPTILES

#### Snakes

Of the 3000 species of snakes, approximately 10% to 15% are venomous. Of the 14 families of snakes, four contain venomous species. Snakes are distributed throughout most of the earth’s surface, including fresh and salt water. The major exceptions are the Arctic and Antarctic zones, New Zealand, Malagasy, and many small islands. Most snakebites occur in tropical and subtropical climates, especially in agricultural settings where the inhabitants go barefoot. Sea snakes are found only in the Pacific and Indian Oceans. Snakes are poikilotherms, which accounts for their distribution and activity. Their inability to raise their body temperature above ambient levels restricts their activity to a fairly narrow temperature range, approximately 25° to 35°C. All snakes are carnivorous, and their venom apparatus evolved for the purpose of obtaining food.

#### Epidemiology

The incidence of reported venomous snakebites in the United States is greatest in the South. States having the highest death rates are North Carolina, Arkansas, Texas, and Georgia. Of all snake bites, 97% occur on the extremities, with two-thirds on the upper extremities and one-third on the lower extremities. This reversal of historical distribution may reflect bites being provoked rather than accidental. Bites that occur accidentally are considered “illegitimate,” whereas bites that occur during attempts to handle or disturb a snake are considered “illegitimate.” Men are bitten nine times more frequently than women.

Imported venomous snakes have recently been an increasing problem throughout the United States. In the past, only zoos, research centers, and herpetologists kept exotic venomous snakes. Today, hundreds of people are raising deadly venomous snakes without the necessary precautions, such as specialized cages, safe handling techniques, and rapid access to specific antivenom. They place not only themselves, but also their families and the general public, in danger.

#### Classification and Characteristics

The four venomous families of snakes are the Colubridae, Elapidae, Viperidae, and Atractaspididae. The Colubridae, although representing 70% of all species of snakes, have very few venomous members dangerous to humans; these include the boomslang and bird snake. They are rear-fanged snakes, and although many possess venom, they generally do not envenomate humans. The Elapidae are more common and include the cobras, kraits,
CHAPTER 55
Venomous Animal Injuries

The other major group of venomous snakes in the United States is the coral snakes. The eastern coral snake (*Micrurus fulvius*) is found in North Carolina, South Carolina, Florida, Louisiana, Mississippi, Georgia, and Texas. There are two subspecies that have similar clinical presentations and will be discussed together. The western or Sonoran (*Micruroides euryxanthus*) coral snake is native to Arizona and New Mexico. Although both species are generally quite shy unless handled, the eastern coral snake is considered deadly. There are no records of fatalities caused by the western species.

Coral snakes can be readily identified by their color pattern. At first glance, they resemble one of several varieties of king snake found in the southern United States. The coral snake can be differentiated from the king snake by two characteristics: the nose of the coral snake is black, and the red and yellow bands are adjacent on the coral snake but separated by a black band on the king snake (Figs. 55.1 and 55.2). The popular rhyme is as follows:

*Red next to yellow, kill a fellow.*
*Red next to black, venom lack.*

This rhyme can be used only in the United States; venomous Brazilian coral snakes have red next to black bands, and some coral snakes have no red bands.

Identification

There are two key principles for identifying venomous snakes: Only experts should handle live snakes, and even dead snakes can envenomate careless handlers. It is not difficult to differentiate between pit vipers and harmless snakes found in the United States (Fig. 55.3). Pit vipers, as their name implies, have a characteristic pit midway between the eye and the nostril on both sides of the head. This pit is a heat-sensitive organ that enables the snake to locate warm-blooded prey. Pit vipers may be identified through other methods, but this characteristic is very consistent. The triangular shape of the head, the presence of an elliptical pupil, the tail structure, and the presence of fangs are useful characteristics but are inconsistent. The arrangement of subcaudal plates may be used for Crotalinae if the head has been damaged or is unavailable. An individual specimen may not fit the classic description, depending on the age of the snake, the time of the year, and the condition of the tail and mouthparts. Neither color nor skin pattern is a reliable method of identifying pit vipers (Fig. 55.4).

Size is not an important factor in identifying various reptiles. Venomous snakes range in length from several inches to several feet. Although a 6-foot eastern diamondback rattlesnake is much more dangerous than a 10-inch copperhead, all venomous snakes are able to envenomate from birth and should be treated as though they are dangerous.

Exotic snakes that are not pit vipers are not as easily identified. If possible, they should be safely transported to an expert for positive identification. Local zoos, herpetologists, poison control centers, and universities often have individuals who can identify unknown snakes.

Other Reptiles

Only two venomous lizards are found in the world, both in the southwestern United States and Mexico. They are the Gila monster (Heloderma suspectum) and the Mexican beaded lizard (Heloderma horridum). Fortunately, both these lizards are nonaggressive and rarely encountered. Bites usually result from handling the animals in captivity. The Gila monster and the Mexican beaded lizard are easily identifiable. Both have thick bodies, beaded scales, and either white and black or pink and black coloration (Fig. 55.5).

Toxins

The two main factors influencing the pathophysiology of any venomous animal injury are the toxic properties of the venom and the victim’s response to these toxins. In the past, snake venoms were classified as either neurotoxic or hematotoxic, depending on the observed response of the victim to the various venoms. Modern toxicologic investigation has shown that this classification is inadequate because most snake venoms studied contain
that are much smaller than those of pit vipers. The fangs in most snakes are shed and replaced regularly, and it is not unusual to see a snake with double fangs on one or both sides of its mouth.

The snake can control the amount of venom injected. In biting a human, a prey much too large to swallow, the snake may inject little or no venom (a “dry” bite), especially if injured or surprised. However, the snake may inject more than 90% of the contents of the gland for the same reasons.

Clinical Features

The signs and symptoms of a venomous snakebite vary considerably and depend on many factors. Up to 50% of venomous snakebites result in little or no envenomation. A person with impaired cardiovascular, renal, or pulmonary function is less able to cope with even a moderately severe envenomation. Because of these multiple variables, the individual clinical response is the only way to judge the severity of a venomous snakebite. Factors that influence the effects of a snakebite are the age, health, and size of the snake; the relative toxicity of the venom; the condition of the fangs; whether the snake has recently fed or is injured; the size, age, and medical problems of the victim; and the anatomic location of the bite.

Local envenomation, if left untreated, can cause serious systemic problems (eg, disseminated intravascular coagulation, pulmonary edema, and shock) as the toxic products are absorbed. The victim’s autopharmacologic response to the envenomation must also be taken into account. An immunoglobulin E (IgE)–mediated anaphylactic-type reaction may develop in victims of a previous snakebite when reexposed to the venom. Many venoms contain enzymes that trigger the release of bradykinin, histamine, and serotonin from the patient’s cells, which may cause fatal anaphylactoid reactions. A wave of effects ranging from minimal pain to multisystem failure and death can occur over a period of several days.

Pit Vipers

The most consistent symptom associated with pit viper bites is immediate burning pain in the area of the bite, whereas pain may be minimal with bites of Elapidae and other exotic snakes. With pit vipers, the severity of pain is probably related to the amount of venom injected or the degree of swelling. Edema surrounding the bite that gradually spreads proximally is a common finding. This edema is usually subcutaneous, begins early, and may involve the entire extremity. Compartment syndrome has been described; however, a true compartment syndrome is unusual even with severe edema. It has been reported more frequently in models involving intracompartmental venom injection. Most fangs do not penetrate into the fascial compartments but subcutaneously, although muscle destruction may result from direct toxicity. Mortality is less frequent with distal bites to the toe and finger and is greatly increased with intravenous bites. An intravenous bite from any venomous snake is likely to be fatal. Petechiae, ecchymosis, and serous or hemorrhagic bullae are other local signs, which trend to be more pronounced with patients on anticoagulant therapy.

Necrosis of skin and subcutaneous tissue is noted later and may result from inadequate doses of antivenom. Many systemic symptoms, such as weakness, nausea, fever, vomiting, sweating, numbness and tingling around the mouth, metallic taste in the mouth, muscle fasciculations, and hypotension, often occur after pit viper envenomation.

Death from pit viper bites is associated with disruption of the coagulation mechanism and increased capillary membrane permeability. Ultimately, these two processes lead to massive pulmonary edema, shock, and death. Heart and kidney damage occur secondary to these mechanisms. Specific toxins in certain species
may act directly on specific organs, such as the heart or skeletal muscle. An allergic type of reaction may add to this process through release of histamine and bradykinin.12

Coral Snakes
Signs and symptoms can vary considerably with bites of coral snakes, Mojave rattlesnakes, and many exotic snakes, especially cobras and Australian elapids. Little pain and swelling may occur. Many of these species’ venoms contain compounds that block neuromuscular transmission at acetylcholine receptor sites and have direct inhibitory effects on cardiac and skeletal muscle. Ptoxis is common and often the first outward sign of envenomation. Other signs and symptoms include vertigo, paresthesias, fasciculations, slurred speech, drowsiness, dysphagia, restlessness, increased salivation, nausea, and proximal muscle weakness. The usual cause of death is respiratory failure.

Gila Monster
Gila monster bites are generally associated with pain, edema, and weakness. Hypotension is common with severe bites. Envenomation involves secretion of the venom from glands along the lower jaws. The venom is introduced into the victim through grooved teeth and a chewing mechanism. There are no reported deaths from Gila monster bites, although myocardial infarctions have been reported.

Infection
Although snakebite envenomation has been stressed here, any bite or puncture wound carries a risk for bacterial contamination. Gram-negative organisms predominate when snake venom and mouthparts are cultured. Although several studies have shown that prophylactic antibiotics are not indicated for snakebite, tetanus, osteomyelitis, cellulitis, or gas gangrene may occur in cases of snakebite with or without envenomation. This is especially true when a large amount of local tissue destruction has occurred, treatment has been delayed, or inappropriate first aid was attempted.

Differential Diagnoses
The differential diagnosis of venomous snake bites include dry bites, bites from nonpoisonous snakes, spider and tick bites, scorpion and hymenoptera stings, dermatological disorders such as toxic epidermal necrolysis (TEN), Stevens-Johnson syndrome, and methicillin-resistant Staphylococcus aureus (MRSA) infections.

Diagnostic Testing
Ultrasoundography can be used to assess the extent of the dermatologic involvement and depth of the snakebite.11 An electrocardiogram, complete blood count, urinalysis, prothrombin time, and levels of fibrinogen, fibrin split products, electrolytes, blood urea nitrogen, and creatinine are recommended; blood should be typed and cross-matched for 4 units of packed red blood cells. Enzyme-linked immunosorbent assay (ELISA) testing can be performed for the specific species of rattlesnakes, but the turnaround time is too delayed to have any clinical impact in the ED.14

Management
Out-of-Hospital Care
All snakebites are considered an emergency, and any victim should be medically evaluated. The initial 6- to 8-hour period after a snakebite is critical. During this time, medical therapy can help prevent the morbidity associated with severe envenomation. Effective out-of-hospital care can be important.15

Out-of-hospital care is relatively simple if guided by four basic concepts. First, the estimated time until arrival at a medical facility, as well as the skill of the on-scene assistants, must be considered when first aid is instituted. Separate the victim from the snake if possible to prevent further bites. A stick, pole, or other object longer than the snake can be used to move the snake away from the victim or, if necessary, to kill the snake by striking it behind the head. Rapid transportation to a medical facility is the best first aid for a snakebite. Any constricting jewelry or clothing should be removed from an extremity to prevent a tourniquet effect proximal to the swelling.

Second, spread of the venom should be slowed if possible; several methods are known. The patient’s excitement and physical activity, movement of the bitten area, alcohol consumption, and greater depth of the bite may increase the spread of venom. Except for the last factor, these issues can be addressed by calming the victim, immobilizing the bitten area with a sling or splint, and not giving anything by mouth. A method of first aid for venomous snakebites that was developed in Australia—the immobilization and compression technique (also called the Commonwealth Serum Laboratory technique)—slows uptake of Elapidae venom and mock venom in humans. The bitten extremity is either wrapped in an elastic bandage or placed in an air splint. In another technique from Australia called the Monash method, a thick pad and bandage are placed over the bite wound and extremity. Both of these techniques have similar postulated mechanisms of action: The lymphatic vessels and superficial veins are collapsed, and the proximal spread of venom is slowed. Although this method is successful as first-aid therapy for Elapidae and coral snakebites, its use for pit vipers has not been demonstrated.16 If less than 30 minutes has elapsed since the bite, a constricting band applied tightly enough to impede superficial venous and lymph flow, but not arterial blood flow, may be used. The band is applied loosely enough to admit a finger between the band and the skin after application. It is used with caution to prevent the development of a tourniquet effect under swollen tissue, which may cause more local tissue destruction than the snakebite. Incision of bite wounds has no proven efficacy and poses potential danger to underlying structures and therefore is not recommended. The use of ice is not helpful in slowing the spread of venom, but an ice bag wrapped in a towel and applied to the bite area helps relieve pain. Ice water immersion or cryotherapy and packing of the extremity in ice are not recommended and only contribute to tissue destruction. The use of commercial suction devices has not been shown to be beneficial.17

Third, when feasible, snakes should be identified when possible, although this should not delay transport of the patient to definitive medical care. Identification of the snake must be done safely—usually only by someone expert in handling snakes. If the snake is indigenous to the area, identification is usually not necessary because the treatment protocol is the same, particularly with pit vipers. A photo may be useful in identifying the snake if a close-up of the head and tail are included. Dead snakes can be placed in a hard container, such as a bucket or ice chest. Care should be taken to not touch the head of the snake because envenomation can occur even after death.

Fourth, additional medical interventions, if available, should be initiated, including cardiac monitoring, intravenous fluids, and analgesics.

Emergency Department Care
Many snakes do not envenomate the victim when they bite, which has provided false support for the historical folk lore use of
whiskey, clam juice, or chickens in the treatment of snakebite. The only proven therapy is antivenom. Emergency care of a snakebite focuses on supportive care and rapid treatment with the appropriate antivenom. Rapid decision-making is required to determine the optimal type, amount, and route of administration of the antivenom. By the time the emergency clinician examines a snakebite victim, the venom may have already caused much damage, both locally and systemically. In this case, the emergency clinician must be prepared to support the victim's cardiovascular and respiratory systems.

**Patient History.** Specific historical information includes time elapsed since the bite, the number of bites, whether first aid was administered and what type, location of the bite, and symptoms (eg, pain, numbness, nausea, tingling around the mouth, metallic taste in the mouth, muscle cramps, dyspnea, and dizziness). A brief medical history includes the last tetanus immunization, medications, and cardiovascular, hematologic, renal, and respiratory problems. An allergy history with emphasis on symptoms after exposure to horse or sheep products, previous injection of horse or sheep serum, and a history of asthma, hay fever, urticaria, or allergy to wool, papain, chymopapain, papaya, or pineapple should be obtained if antivenom treatment is being considered.

**Patient Examination.** The bite area is examined for signs of fang marks or scratches and local envenomation (eg, edema, petechiae, ecchymosis, and bullae). The area distal to the bite is checked for pulses. A general physical examination is performed, with emphasis on the cardiorespiratory system and the neurologic examination, especially if a Mojave rattlesnake, coral snake, or exotic snake is suspected. If the bite involves an extremity, the circumference of the extremity at the site of the bite and approximately 5 inches proximal to the bite should be measured and recorded. These data aid in objectively estimating both spread of the venom and the effect of antivenom (Fig. 55.6).

**Initial Medical Care.** If the bite occurred less than 30 minutes before arrival in the ED, first-aid measures can be instituted, including a constricting band until antivenom can be obtained. Snakebite victims with clinical evidence of envenomation should have an intravenous line with normal saline placed

---

**Fig. 55.6.** A and B, Northern copperhead (*Agkistrodon contortrix mokasen*) bite on right hand with normal left hand for comparison. C, Northern Copperhead bite to upper extremity showing diffuse swelling, and hemorrhagic bullae formation.
in an unaffected extremity. The patient’s vital signs are monitored closely. Snakebite victims may be hypotensive because of third-space losses and hemorrhage. In an edematous extremity, the distal pulse may have to be examined with a Doppler instrument. If a compartment syndrome is suspected, insert a pressure monitor and obtain surgical consultation. If signs and symptoms of true compartment syndrome are present, pressure greater than 30 mm Hg may indicate the need for a fasciotomy; however, there is evidence that administration of antivenom is much more efficacious in lowering compartment pressures.15,12

Once stabilization is initiated, the severity of the bite must be determined and a decision made regarding whether to administer antivenom. The more distal the bite on the extremity, the less toxicity associated with the bite. Intravenous bites may be rapidly fatal. Bites occurring on the trunk, neck, and face have increased risk because of rapid transit of the venom.

**Antivenom.** The emergency clinician must determine the type of antivenom to administer, how much, and over what period. If the bite is from a pit viper, the problem is not too difficult. Bites from copperheads usually cause a moderate amount of edema but generally do not require antivenom, although it may be indicated in selected cases.18 Envenomation may be classified according to severity into five grades, from grade 0 (no sign of envenomation) to grade IV (very severe envenomation). The amount of antivenom can be correlated with the grade of envenomation:

- **Grade 0 (minimal):** There is no evidence of envenomation, but snakebite is suspected. A fang wound may be present. Pain is minimal, with less than 1 inch of surrounding edema and erythema. No systemic manifestations are present during the first 12 hours after the bite. No laboratory changes occur.
- **Grade 1 (minimal):** There is minimal envenomation, and snakebite is suspected. A fang wound is usually present. Pain is moderate or throbbing and localized to the fang wound, surrounded by 1 to 5 inches of edema and erythema. No evidence of systemic involvement is present after 12 hours of observation. No laboratory changes occur.
- **Grade II (moderate):** There is moderate envenomation, more severe and widely distributed pain, edema spreading toward the trunk, and petechiae and ecchymoses limited to the area of edema. Nausea, vomiting, and a mild elevation in temperature are usually present.
- **Grade III (severe):** The envenomation is severe. The case may initially resemble a grade I or II envenomation, but the course is rapidly progressive. Within 12 hours, edema spreads up the extremity and may involve part of the trunk. Petechiae and ecchymoses may be generalized. Systemic manifestations may include tachycardia and hypotension. Laboratory abnormalities may include an elevated white blood cell count, creatine phosphokinase, prothrombin time, and partial thromboplastin time, as well as elevated fibrin degradation products and D-dimer. Decreased platelets and fibrinogen are common. Hematuria, myoglobinuria, increased bleeding time, and renal or hepatic abnormalities may also occur.
- **Grade IV (very severe):** The envenomation is very severe and is seen most frequently after the bite of a large rattlesnake. It is characterized by sudden pain, rapidly progressive swelling that may reach and involve the trunk within a few hours, ecchymoses, bleb formation, and necrosis. Systemic manifestations often commencing within 15 minutes of the bite, usually include weakness, nausea, vomiting, vertigo, and numbness or tingling of the lips or face. Muscle fasciculations, painful muscular cramping, pallor, sweating, cold and clammy skin, rapid and weak pulse, incontinence, convulsions, and coma may also be observed. An intravenous bite may result in cardiopulmonary arrest soon after the bite.

Dart and colleagues have advocated slightly different grading systems and higher doses of antivenom: Grades 0 and I correspond to *minimal* envenomation, grade II represents *moderate* envenomation, and grades III and IV correspond to *severe* envenomation.19,20 Either system can be used interchangeably.

Onset of symptoms after a pit viper bite may be delayed and may involve a variety of neurologic symptoms, including weakness, ptiosten, stupor, bulbar paralysis, and other cranial nerve dysfunction, as well as nausea, abdominal pain, and headache.21,22

**Administration of Antivenom.** Any victim of a venomous snakebite with moderate or severe envenomation is a candidate for antivenom. The choice of antivenom depends on the species of snake, and the antivenom may be horse serum– or sheep-derived Fab fragments. Wyeth Laboratories, producer of the polyvalent horse serum–derived antivenom for Western Hemisphere pit vipers, no longer manufactures that antivenom. Many zoos and hospitals still maintain vials of this antivenom, but most have replaced this with the ovine-derived Fab antivenom (FabAV). This antivenom is derived from four species of pit vipers in the United States and has not been clinically studied with regard to bites from Mexican, Central American, or South American pit vipers.20,23 There is a reported case of a patient bitten by a South American rattle snake who was successfully treated with FabAV.24

Most antivenom for exotic snakes and the eastern coral snake is derived from horse serum. A recent polyvalent Fab(2) antivenom derived from horse serum and produced in Mexico has been shown to be effective against both North and South American crotalid species.25 Skin testing was commonly performed before administration of horse serum–derived antivenom, but it is not medically indicated because of the inaccuracy of the test. Moreover, testing with normal horse serum may precipitate an allergic reaction, and even a positive test result may not preclude treatment if a patient has sustained severe envenomation. The incidence of allergic reactions with FabAVs has been much less than previously seen with whole immunoglobulin G (IgG). The incidence of allergic reactions was 17% for early reactions and 12% for late reactions in postmarketing analysis. This was thought to be a result of incomplete purification of one lot contaminated by Fc fragments. Most of these reactions were minor and did not require stopping the infusion of the antivenom. The true incidence is unknown.26-29

**Dosage and Precautions.** Current treatment of pit viper envenomation in the United States is to use a FabAV polyvalent antivenom rather than the horse serum product.20 This is designed to limit the allergic reactions associated with horse serum antivenom by use of antigen-binding fragments (fabs) of sheep (ovine) immunized against four species of venomous snake found in the United States. CroFab has been shown to be as effective as the Wyeth antivenom with fewer allergic reactions. Because of more rapid clearance of smaller Fab fragments by the kidney, however, a repeat-dose regimen must be used to prevent the recurrence of coagulopathy. Reported adverse side effects of FabAV polyvalent antivenom include subacute coagulopathy, thrombocytopenia, and ischemic stroke.31-33 The duration of action of the venom may be longer than the therapeutic effect of the antivenom. Initial studies have shown promise for a new affinity-purified, mixed monoclonal antivenom that has been tested with favorable results in humans after minimal to moderate crotalid envenomation.30 Its efficacy in pit vipers from South America or Asia has not been proved. Purification of antivenom by separation of active fractions may lead to safer administration of horse serum–derived antivenom. An algorithm has been developed that can aid in decision-making after a crotalid bite (Table 55.2 and Fig. 55.7).30

In the next decade, snakebite management will probably change radically throughout the world. Phytotherapy (botanical therapy)
and other non-antivenom drug therapies for snakebite have shown promise in experimental animal studies, and some centers have successfully treated snakebite with medical support only. Hyperbaric oxygen therapy has also been used as an adjunct to antivenom in the treatment of venomous snakebite; however, there is insufficient evidence to recommend its use.34

The following are general guidelines to maximize patient care when antivenom is used:

1. Because anaphylaxis may occur whenever antivenom is administered, appropriate therapeutic agents (eg, oxygen supply, airway support, epinephrine, corticosteroids, and other pressors) must be ready for immediate use. Any patient requiring antivenom should have two intravenous lines inserted. If an allergic reaction occurs, the line with the antivenom can be clamped and the other line used for resuscitation. Administration of 0.3 mg of 1:1000 epinephrine subcutaneously before administration of antivenom may prevent allergic reactions to horse serum–derived antivenom and, if not contraindicated, should be used. If an allergic reaction occurs, then the epinephrine can be given intramuscularly as needed.

2. The initial dose of antivenom is prepared. The smaller the body of the patient, the larger the relative initial dose that may be required. A bitten child usually receives more venom in proportion to body weight and thus requires more antivenom to neutralize it. Because children seem to have less resistance and less body fluid with which to dilute the venom, they may require twice the adult dose of antivenom. The total fluid requirements of children are lower, however, so the antivenom is given in a more concentrated solution. All antivenom is administered intravenously.35

3. Pregnancy is not a contraindication to antivenom therapy.

4. Administration of antivenom at or around the site of the bite is not recommended.

5. The need for subsequent doses is based on the patient’s clinical response. The patient is monitored closely after the initial dose, and local and systemic symptoms, as well as laboratory findings, are determinants of the need for further antivenom. Additional injections of one to five vials of antivenom are administered every 1 or 2 hours if symptoms progress. Most pharmacies do not stock large amounts of antivenom, and the pharmacy should be notified to obtain additional antivenom for treating a severe bite. Continuous infusions of Crotalidae polyvalent Immune Fab (ovine) FabAV has been used in selected North American rattlesnakes.36

6. Even with a history or signs of allergy, patients with severe envenomation are treated with a dilute form of antivenom and epinephrine to maximize antivenom administration but minimize allergic symptoms.

Coral and Exotic Snakes. It is recommended that all victims of bites by the eastern coral snake (Micrurus fulvius) be

*Dosage based on initial findings and clinical response to antivenom (see also Fig. 55.7).

†If this dose elicits a clinical response, it is recommended that an additional two vials be given at 6, 12, and 18 hours. The patient’s coagulation studies should be followed to determine additional amounts.

FabAV, Fab antivenom.

---

**Fig. 55.7.** Algorithm for use of Fab antivenom (FabAV) (antivenom).
Other Envenomation. Gila monster and Mexican beaded lizard bites are treated similarly to pit viper bites with regard to first aid. No definitive medical treatment exists. Antivenom is currently not available. Local wound care, tetanus prophylaxis, the use of antibiotics and analgesics, and supportive care are the extent of ED treatment available for this type of envenomation.

Envenomation by the yellow-bellied sea snake causes severe muscle necrosis with the release of large amounts of myoglobin and neurologic symptoms. Although a polyclonal antivenom is available from Australia, airway control, maintenance of adequate urine output, alkalinization of urine, and general supportive care are usually sufficient.

Disposition

If no envenomation is evident after clinical examination and the snake was either nonvenomous or a pit viper, the victim can be observed for 6 to 8 hours. With some snakebites, however, toxicity may be delayed by up to 8 hours. If no sign of envenomation is seen after 8 hours, the patient may be discharged. These patients require tetanus immunization when indicated, wound care instructions, and referral for follow-up within 24 to 48 hours. They require instructions on the types of delayed symptoms that may occur and when to return to the ED. If only local pain and minimal edema have occurred, the patient is closely watched for 12 hours in the ED. If the pain and swelling decrease and no systemic symptoms or laboratory abnormalities develop, the patient may be treated with the same precautions as a patient with no signs of envenomation. Any patient with moderate or severe envenomation should be admitted to an intensive care unit for monitoring during antivenom therapy. Depending on the severity of the bite, blood products, vasopressors, and invasive monitoring may be necessary.

Any patient bitten by a coral snake, a Mojave rattlesnake, or an exotic snake is at risk for severe neurologic sequelae that may not become evident for many hours. As a result, these patients require hospital admission, preferably to an intensive care unit where they can be monitored closely for up to 24 hours. Arrangements should be made to have a ventilator, invasive monitoring, and dialysis equipment available if necessary. Appropriate antivenom should be obtained and treatment initiated at the earliest onset of symptoms. Some experienced clinicians may wait until symptoms develop before administering antivenom. All patients receiving antivenom require close monitoring for recurrence of coagulopathy, which may occur several days after initial envenomation. The overall disability of patients surviving snake envenomation is low including chronic pain at the bite site, extremity paresthesias, and focal weakness.

VENOMOUS ARTHROPODS

Arthropods are animals with segmented bodies and jointed appendages. This phylum (Arthropoda) contains approximately 80% of all known animals. The living members of this phylum are categorized into 12 classes. Two classes, the Insecta and the Arachnida, are of particular interest because numerous venomous species have evolved that are harmful to humans. Many species have developed venom glands and an apparatus for delivering the venom to obtain food. Others have developed venom delivery systems used solely for defense; most of these species are found in the orders Hymenoptera and Lepidoptera.

Arthropods account for a higher percentage of deaths from envenomation than do snakes. They are found inside dwellings, as well as in deserts, forests, and lakes. Although most arthropods are more active during the warmer months, many are active throughout the winter. Arthropods are also active 24 hours a day, and many can fly, thus increasing their range. This high level of
contact results in millions of cases of envenomation annually. Most fatalities result from an autopharmacologic response by the victim rather than the toxicity of the venom. An individual stung by a bee may have a small amount of pain and local swelling or, in severe cases, an anaphylactic reaction and death.

Arthropods use three main methods of delivering venom: stinging, biting, and secreting venom through pores or hairs. Some arthropods combine two systems, one for offense and the other for defense. In general, venom systems found on the oral pole of an animal are used for offensive purposes or food acquisition, whereas systems found on the caudal pole are used for defense. Humans are not considered prey for any venomous arthropod, and therefore bites from them are defensive, accidental, or reflexive. Many venomous arthropods are omitted from this discussion because of their infrequent contact with humans or the relative impotence of their venom.

**Hymenoptera**

Hymenoptera is a familiar order of arthropods that is composed of the families of bees, wasps, hornets, yellow jackets, and ants. Many of these species are social insects, and their defense response is related to protection of the group rather than the individual organism. Although most members of this order are stinging insects, several species of ant can bite and sting simultaneously.

Bees and wasps have similar mechanisms of delivering venom. Female insects of this type have modified ovipositors that protrude from the abdomen and act as hypodermic needles to administer the venom. The barbed stinging apparatus of the bee is quite prominent. The stinging action pulls the stinger from the bee, thereby eviscerating the insect and killing it.

The wasp, which has an unbarbed stinger, may inflict many stings without damaging itself or its stinging apparatus. The venom is produced in one or two tubular glands that empty into a venom reservoir. The venom reservoir has a duct that connects to the stinger. The venom is composed of several classes of substances varying in composition among different species. Proteins, as in snake venom, make up most of the venom by dry weight. Peptides, amino acids, carbohydrates, lipids, and other low-molecular-weight substances are also found. The most common enzymes are phospholipase A and hyaluronidase. Peptides are common in some species and constitute up to 50% of the dry weight. Most of the toxicity of the venom results from substances of low molecular weight (e.g., bradykinin, acetylcholine, dopamine, histamine, and serotonin). Many other antigenic substances have been identified in bee and wasp venom, and they account for the induction of hypersensitivity and anaphylaxis in humans. In the United States, 10% of all cases of anaphylaxis are attributed to stinging insects or hymenoptera.41

**Clinical Features**

The signs and symptoms of bee and wasp stings vary, depending on the degree, type, and location of envenomation, as well as the characteristics of the victim. Bee and wasp venom can cause serious injury other than allergic types of reactions, depending on the number of stings, the species of insect, the size and previous health of the victim, and the anatomic area stung. For example, a stinger in the tongue or throat may quickly compromise the airway. Honeybee venom causes a much greater release of histamine per gram than does other hymenoptera venom and thus is more dangerous. Certain species of honeybee release a pheromone, isoamyl acetate, when the ovipositor is pulled from the abdomen after stinging a victim. This pheromone attracts other bees to the victim and thus incites multiple stings.

There is little antigenic overlap among species, which may explain the variability in reaction to stings reported by victims. Victims who are allergic to honeybees and who mistakenly identify a yellow jacket as a honeybee may not have a systemic reaction and thus may think that they are no longer allergic to honeybees.

The most consistent finding is immediate pain at the site of the sting, followed by local swelling, redness, and itching. A sensitive victim may experience swelling, urticaria, coughing, wheezing, coma, and respiratory arrest. Some large and especially venomous hornets have been known to cause muscle necrosis, rhabdomyolysis, and renal damage. Additionally, cerebrovascular accidents, intracranial bleeds, and myocardial infarction have been described.42 Most serious reactions to bee stings occur in the first 30 minutes; however, the local effects of a sting may persist for 2 or 3 days. Delayed hypersensitivity may occur 7 to 10 days after the sting.43-45

**“Killer Bees.”** Health officials have been concerned about a particularly aggressive species of bee imported from Africa to Brazil in 1956 to increase honey production that has been known to attack humans and cattle with fatal results. This bee has managed to compete with native species and is gradually replacing some of these species while still retaining its aggressive behavior. Envenomation from these aggressive arthropods is a public health issue and most dangerous to very young or elderly patients and those with concomitant medical conditions.46 Killer bees have colonized northern Mexico and have moved into the southern United States, including California, Arizona, and Texas, where the mean high temperature is at least 60°F. This type of bee is not more toxic, only more aggressive (Fig. 55.8).

**Fire Ants.** Another unwelcome import to the United States is the fire ant. This insect is a member of the family Formicidae and is another of the Hymenoptera that is harmful to humans. Several species of fire ant are known, some native to North America and some imported. The species responsible for 95% of clinical cases, *Solenopsis invicta*, was imported from Brazil to Alabama in the 1930s. This ant is now found in nine southern states and is replacing many native species and inhabiting new niches. The only limiting factor keeping the fire ant from progressive migration seems to be cold winters. This ant is small and light reddish brown to dark brown. Its venom is unique to the animal kingdom in that it is 99% alkaldoid. The remaining 1% is quite immunogenic and can sensitize an individual to the venom. Properties of this venom include hemolysis, depolarization of membranes, activation of the alternative complement pathway, and general tissue destruction. The sting is produced when the ant bites the victim with its jaws and, while holding tight, pivots around and stings the victim with its ovipositor. The sting usually produces a sterile pustule within 24 hours. Other symptoms include local burning, redness, and itching. With multiple stings and in sensitive individuals, urticaria, angioedema, dyspnea,
nausea, vomiting, wheezing, dizziness, and respiratory arrest may occur. Approximately 10% of victims have some degree of hypersensitivity reaction.44

Differential Diagnoses

The differential diagnosis of hymenoptera envenomation includes stings from honeybees, wasps, hornets, yellow jackets, fire ants, scorpions, centipedes, millipedes, caterpillars, spider bites, infectious causes such as cellulitis, and other allergic reactions, including anaphylaxis and contact dermatitis.

Diagnostic Testing

Most cases of hymenoptera stings with localized reactions require no diagnostic studies. Severe reactions, infections, and anaphylaxis should have a complete blood count, serum electrolytes, and an acid-base status assessed. Those demonstrating severe allergic reactions should be referred for more comprehensive allergy skin testing.

Management

Prehospital Care. First aid for Hymenoptera envenomation depends on the degree of reaction to the sting. For simple stings, an ice bag wrapped in a towel and applied to the sting area usually relieves the pain and swelling. In the event of an anaphylactic reaction, basic life support is administered until further medical help arrives. Many people allergic to Hymenoptera envenomation carry an emergency insect sting kit containing a tourniquet, epinephrine, and an antihistamine. These kits are readily available, and both the patient and the patient’s family should be instructed in the treatment of a severe allergic reaction.

Emergency Department Care. No specific antivenom exists for Hymenoptera stings. Treatment consists of local wound care and general supportive measures. A history of any previous allergic reactions to bee stings, hay fever, asthma, or drug reactions is obtained. The circumstances surrounding the sting and the number and location of stings are noted. In patients with a single sting and only a local reaction, the sting area is inspected for a tourniquet, epinephrine in a 1:1000 dilution, and an antihistamine. These kits are readily available, and both the patient and the patient’s family should be instructed in the treatment of a severe allergic reaction.

Disposition

The patient is monitored, and if no further reaction is observed, he or she may be discharged with instructions to return to the ED if wheezing, dyspnea, hives, dizziness, or dysphagia occurs. Any patient requiring epinephrine should be watched for at least 6 hours and may require 23-hour observation if symptoms recur. There is a possibility of recurrence of the reaction up to 72 hours, and patients should be warned of this in their discharge instructions. Patients with allergic reactions to a single sting should be given an emergency insect sting kit and instructed in its use and referred to an allergist for desensitization. Patients seen in the ED with systemic reactions to stings should be referred for skin testing and immunotherapy and desensitization.45

Spiders and Scorpions

The class Arachnida contains the largest number of venomous species known, with approximately 34,000 species of venomous spiders and 1400 species of venomous scorpions. Virtually all known species are venomous, but most are not harmful to humans. Only approximately 50 species of arachnids in the United States cause human illness, because most species do not have fangs or stingers sufficiently long to penetrate human skin. Humans fear spiders and scorpions, for good reason in certain cases. Ticks, which also belong to this class, are less feared but probably cause more morbidity because of transmission of infectious diseases, such as Rocky Mountain spotted fever and Lyme disease. Some spider bites are never diagnosed because of lack of significant symptoms and the fact that they occur while the victim is sleeping. Many non-spider bites are incorrectly diagnosed as spider bites, and unfortunately there is no gold standard for making the diagnosis.

Black Widow Spider

The black widow spider, Latrodectus mactans, may be the most recognized venomous spider in the world. Several other closely related species of Latrodectus, or widow spiders, are found throughout the United States, including Latrodectus hesperus, which is common in Arizona and other western states. The diagnosis and treatment of the bites of all species are the same.

The black widow is found throughout the United States (except Alaska) and in southern Canada. The female is approximately twice as large as the male, and although both are venomous, only the female is able to envenomate humans. The black widow is glossy black, occasionally with red stripes, and has a bright red marking on the abdomen (Fig. 55.9). This marking may have an hourglass shape or may appear only as two spots. Abdominal
markings may vary, and related Latrodectus species may be similar in appearance and toxicity. The combined length of the black widow’s head and abdomen is approximately 1/4 inch, and the spider is approximately 1 1/2 inches long, including the legs. It is found in dark, protected places, such as under rocks, in woodpiles, and in outhouses and stables. The female is not aggressive except when guarding her eggs.

The venom apparatus of the black widow is a modified first appendage of the head known as the chelicera. The spider is able to control the amount of venom injected into its prey. The venom of the black widow is complex and contains both protein and nonprotein compounds.

Spiders normally use the venom to paralyze their prey and also to liquefy the tissues of the prey for digestion. The venom probably evolved from digestive glands analogous to the salivary glands in snakes. The ingredient most toxic to humans is thought to be a neurotoxin. This toxin destabilizes neuronal membranes by opening ionic channels, causing depletion of acetylcholine from presynaptic nerve terminals and increasing the frequency of spontaneous miniature endplate potentials at neuromuscular junctions.

Clinical Features. The classic symptomatology of the black widow bite is initially a pinprick sensation that may be followed by minimal local swelling and redness. If the area is examined closely, two small fang marks may be noticed. Sometimes the bite is not felt, especially if the victim is working when the bite occurs. From 15 minutes to 1 hour later, dull crampy pain develops in the area of the bite and gradually spreads to include the entire body. Usually, the pain is concentrated in the chest after upper extremity bites or in the abdomen after lower extremity bites. The abdomen may become boardlike, and the patient may complain of severe crampy pain. The abdominal manifestation may mimic pancreatitis, a peptic ulcer, or acute appendicitis. Pregnant women may go into premature labor and precipitous delivery. Associated symptoms include dizziness, restlessness, ptosis, nausea, vomiting, headache, pruritus, dyspnea, conjunctivitis, facial swelling, sweating, weakness, difficulty speaking, anxiety, and cramping pain in all muscle groups. Priapism has been reported in children. The patient is usually hypertensive, and cerebrospinal fluid pressure is sometimes elevated.

In adults, the signs and symptoms begin to abate after several hours and usually disappear in 2 or 3 days. A small child bitten by a black widow spider, however, may not survive. As with snake envenomation, the volume of distribution of black widow venom is much smaller in children than in adults. A dose that may cause only a few hours of pain in an adult may lead to complete cardiac decompensation and respiratory arrest in a child. Adult patients with preexisting hypertension, cerebrovascular disease, or cardiovascular disease are also at greater risk for complications. Symptoms usually persist for 8 to 12 hours and then subside, although in severe cases muscle cramps may continue for several days.

Differential Diagnoses. The abdominal manifestation following a black widow spider bite may mimic pancreatitis, a peptic ulcer, renal colic, acute appendicitis, or scorpion stings.

Diagnostic Testing. Patients with symptoms of moderate envenomation, pregnant women, children, and those with preexisting cardiovascular disease or hypertension should have a complete blood count, electrolytes, blood urea nitrogen, creatinine, coagulation studies, urinalysis, and an electrocardiogram. There may be electrocardiographic changes similar to those produced by digitalis.

Management. First aid for a black widow spider bite consists of applying an ice pack to the bite area for relief of pain and transporting the victim to a hospital where supportive, symptomatic, and definitive treatment can be administered. The rescuer should obtain the specimen if possible because many dangerous spiders resemble harmless species and vice versa. The patient is monitored en route to the hospital, and basic life support is initiated if necessary. Bites in the neck or mouth area may cause airway compromise through muscle spasm. ED care consists of obtaining a history of the circumstances surrounding the bite, a description of the appearance of the spider, any significant past medical history, current medications, and allergies to insect bites, horses, or horse serum.

The wound site is inspected for fang marks and cleansed with soap and water. As with any puncture wound, the patient’s tetanus immunization status is assessed.

Symptomatic treatment involves controlling the muscle cramps responsible for most of the discomfort associated with the bite. Diazepam or other benzodiazepines given intravenously are useful for relieving muscle spasms. There is one preliminary report in the literature supporting the benefit of dantrolene sodium both orally and intravenously to provide muscle relaxation for Latrodectus envenomation. However, dantrolene administration has not been shown to be clinically efficacious in more recent studies. Parenteral analgesics may be necessary to control pain; these drugs may affect an already compromised respiratory condition, and therefore their use must be closely monitored.

Latrodectus Antivenom. In general, pediatric patients, pregnant women, and the elderly may need to be given Latrodectus antivenom (Lyovac), which is derived from horse serum. A highly purified equine F(ab)2 antibody black widow spider antivenom has been recently investigated. Clinical judgment is used to adjust for the age and category of patients needing antivenom. Candidates for antivenom include patients with severe envenomation manifesting as seizures, respiratory failure, or uncontrolled hypertension, and patients not responding to other therapy. The dose of the antivenom is one vial diluted in 50 mL of normal saline and administered intravenously over a period of 15 minutes. Precautions for allergic reactions should be taken before antivenom is administered. A dose of subcutaneous 1:1000 epinephrine may prevent allergic reactions when given before horse serum antivenom. This antivenom is also useful with other species of the Latrodectus genus.

Disposition
The patient is observed for approximately 6 hours. If symptoms do not develop and the spider was not positively identified as a

Fig. 55.9. Female black widow spider (Latrodectus mactans) with a red hour-glass marking.
Brown Recluse Spider

Several deaths were attributed to the brown recluse spider, *Loxosceles reclusa*, in the 1950s, primarily in the south-central United States, thus drawing the attention of the medical community. Many species of *Loxosceles* are venomous to humans, and at least five are found in the United States. These spiders are approximately 1 inch long, including leg span, and range in color from tan to dark brown. The most distinguishing mark is a violin-shaped darker area found on the cephalothorax (Fig. 55.10). Close examination may reveal that the brown recluse has three pairs of eyes rather than the usual four.

These spiders, as their name implies, are not aggressive and are usually found under rocks, in woodpiles, and occasionally in attics and closets. Their range is concentrated in the south-central United States, especially Missouri, Kansas, Arkansas, Louisiana, eastern Texas, and Oklahoma. However, they have been reported in several large cities outside this range.

The venom apparatus is similar to that of most spiders, including the black widow. The composition of brown recluse venom has not been completely determined, but sphingomyelinase D is a primary component. The local tissue destructive effects are thought to be primarily caused by hemolytic enzymes and a levarferenol-like substance that induces severe vasoconstriction. The systemic symptoms seem to be an allergic phenomenon and vary according to the individual’s immune response to the venom.

Clinical Features. The symptoms of a brown recluse spider bite are both local and systemic. Initially they are similar to those caused by bites of many other spiders and other conditions. The victim may notice some burning pain in the area of the bite. Some victims do not notice the initial bite at all. Pain usually develops within 3 or 4 hours, and a white area of vasoconstriction begins to surround the bite. A bleb then forms in the center of this area, and an erythematous ring arises on the periphery. The lesion at this stage resembles a bull’s-eye. The bleb darkens, necroses over the next several hours to days, and continues to spread slowly and gravitationally, with involvement of skin and subcutaneous fat. Systemic symptoms include fever, chills, rash, petechiae, nausea, vomiting, malaise, and weakness. Hemolysis, thrombocytopenia, shock, jaundice, renal failure, hemorrhage, and pulmonary edema are the usual signs of severe envenomation. Although rare, fatalities are more common in children, which are most often the result of severe intravascular hemolysis.

Differential Diagnoses. Differential diagnosis of a brown recluse spider bite includes pyoderma gangrenosum, furuncles, viral and fungal infections, and foreign body reactions. The most common mimic of *Loxosceles* or other necrotic spider bite is a MRSA skin infection.

Diagnostic Testing. With significant wounds and systemic symptoms, a complete blood count, metabolic and coagulation profile, and urinalysis are performed. Patients with delayed presentation with a necrotic lesion wound cultures for MRSA. A reduced red blood cell surface glycoporphin analysis has been investigated as a potential biomarker for brown recluse spider exposure.

Management. First aid for a brown recluse spider bite is simple. The specimen is secured if possible and the victim transported to a medical facility. Because the lesion develops over a period of days, there may not be any local treatment of the lesion that is effective. The emergency evaluation involves a history of the circumstances surrounding the bite; the time elapsed since the bite; past history of allergic reactions, medications, or medical problems; and an assessment for systemic toxicity. If a specimen is available, identification may be facilitated by recruiting the help of a local entomologist. If signs of systemic toxicity develop, an intravenous line is placed in an unaffected extremity. Vital signs and urine output are closely monitored. Excision of the lesion has not been shown to aid healing and may be detrimental. Lesions have been known to cause extensive scarring, infection, and necrosis. Bites that are in fatty areas, such as the thigh or buttocks, may cause more extensive necrosis.

Historically, dapsone, 50 to 200 mg/day, was thought to be helpful in preventing local effects of the venom. If used within 48 hours, it may limit the size of the lesion that develops. However, dapsone may cause methemoglobinemia and hemolysis in young children and patients with glucose-6-phosphate dehydrogenase deficiency. As a result, we do not recommend routine use of dapsone in patients suffering brown recluse spider bites. Hyperbaric oxygen has been shown to decrease lesion size in animal models. Analgesics and antibiotics should be used as indicated during the course of the disease, but are generally limited to secondary infections. Hemodialysis may be necessary if acute renal failure develops. Plasma exchange for refractory hemolysis after brown recluse spider envenomation may be required. Surgical consultation should be obtained for evaluation of the wound. In a normal host, allow the wound to run its course before wide excision or skin grafting is performed.

The Instituto Butantan in Sao Paulo, Brazil, and Instituto Bioclin, Mexico, both produce an antivenom for *Loxosceles* bites, but they are not available in the United States.

Disposition. Patients with signs of systemic envenomation require hospital admission for monitoring.

Other Spiders

Several other spiders can cause envenomation but are uncommon in the United States. Some of these spiders are large and can be quite aggressive. Most are imported either intentionally or as...
stowaways on cargo ships. Tarantulas, wandering spiders, funnel-web spiders, pallid spiders, and crab spiders are a few of the imported venomous spiders. Many of these species can cause envenomation similar to that of the brown recluse spider, and some produce neurotoxins.

An outbreak of bites by a species of Tegenaria, known as the hobo or aggressive house spider, has been reported. This species was imported from Europe to the Pacific Northwest. This spider is a small brown spider with a herringbone pattern on its abdomen. The lesions are similar to those caused by the brown recluse spider, but systemic symptoms include headache and weakness. Treatment is largely supportive.

Tarantulas are popular pets in the United States, and most native species are relatively nontoxic. Tarantulas are unusual in that the abdominal hairs can be thrown by the spider and embedded in human skin and the eye. These hairs can cause allergic reactions and severe conjunctivitis and must generally be removed under a slit lamp or by an ophthalmologist.

Antivenom is produced for some of these groups (eg, Brazilian Phoneutria and Australian Atrax species) but is usually available only in the country in which the species is generally found.\(^5\) Emergency care therefore involves symptomatic and supportive treatment. A recent import from Thailand, the cobalt blue tarantula, Haplopelma lividum, is a very aggressive spider with toxic venom.\(^6\)

Scorpions

Scorpions are arachnids that resemble crustaceans and are among the oldest terrestrial animals. Scorpions are found throughout the world, and several species are located in the southwestern United States. Only one species, Centruroides sculpturatus (formerly Centruroides exilicauda), which is found in Arizona, is particularly dangerous. Scorpions are nocturnal predatory animals that usually spend the day under rocks, logs, or floors and in crevices. C. sculpturatus, or the bark scorpion, is found on or near trees (Fig. 55.11).

The scorpion has a tail-like structure that is actually the last six segments of its abdomen. The last segment, or the telson, contains the two venom glands and stinger. The toxicity of scorpion venom varies greatly from species to species. In general, the less dangerous species produce more local reactions, and the more dangerous species cause more systemic reactions. Several proteins have been identified in their venom; some cause hemolysis, local tissue destruction, and hemorrhage. The venom of C. sculpturatus is predominantly a neurotoxin that causes or enhances repetitive firing of axons by activation of sodium channels.\(^4\)

Clinical Features. Envenomation causes severe and immediate pain at the sting site. Local edema and erythema may or may not be present, depending on the species. After envenomation by C. sculpturatus, the victim may have heightened sensitivity to touch in the area of the sting along with local numbness and weakness. The diagnosis is often made by tapping on the site of the sting and causing an increase in pain at the site. Systemic symptoms may then develop, including anxiety, restlessness, muscle spasms, nausea, vomiting, excessive salivation, sweating, itching of the nose and throat, hyperthermia, blurred vision, roving eye movement or nystagmus, myoclonus, priapism, hypertension, hemiplegia, syncope, cardiac dysrhythmias, and respiratory arrest.\(^5\) Various systemic complications may occur, depending on the species of scorpion. Tityus trinitatis scorpion stings from Trinidad cause pancreatitis to develop in 80% of victims. A wave of symptoms sometimes occurs over a 24-hour period, or respiratory failure may develop in the first 30 minutes. As with most envenomations, children are at a greater risk for severe reactions. A grading system has been developed to guide management of bark scorpion stings.\(^6\)

Differential Diagnoses. The differential diagnosis of scorpion stings includes black widow spider bites, centipede stings, and hymenoptera stings, such as a bee, wasps, and fire ants.

Diagnostic Testing. Laboratory testing for symptomatic patients includes a complete blood count, renal function test, serum electrolytes, creatine phosphokinase, lipase, and an electrocardiogram if a potentially cardiotoxic scorpion. A serum Western blot test has been developed that can differentiate various scorpion venoms and thus help with diagnosis of Centruroides species, but it is not commercially available.\(^6\)

Management. First aid for a scorpion sting consists of applying an ice bag to the area of the sting and transporting the victim to the hospital. A history of the circumstances surrounding the sting, any previous medical problems, and a description of the scorpion if no specimen is present should be obtained. It is relatively difficult for a layperson to differentiate the various scorpions. Anascorp (Centruroides [scorpion] immune F[ab]2 equine injection) is horse serum derived and has been shown to be effective and safe in both blinded and open studies of patients. It was effective in children if given within 4 hours of the sting.\(^6\) However, most patients will not require antivenom therapy for bark scorpion (Centruroides) stings. Epinephrine 1:1000 can be given before Anascorp to prevent allergic reactions, although the incidence should be less than with whole immunoglobulin. Opioids and benzodiazepines have been shown to be clinically beneficial in controlling pain.\(^5\)\(^8\)

Approved antivenom is recommended in all cases of severe envenomation. Intravenous diazepam or another benzodiazepine may be used for myoclonus and muscle spasms. Phenobarbital, previously used in large doses in children, may be more dangerous than efficacious and may have contributed to deaths in the past. Atropine may be administered to control hypersalivation and bradycardia. Nitroprusside and prazosin have been used to control hypertension. Ventilatory assistance may be necessary, especially in children.\(^5\)

Disposition

It is recommended that victims with systemic symptoms be observed for 24 hours, and children should be admitted to the
hospital for monitoring. Patients with localized pain at the site of the sting can be given pain medications and discharged home with wound care instructions.

Other Arthropods

Ticks are vectors of human disease, and certain pregnant female ticks also secrete a toxin that causes a progressive ascending paralysis in humans and animals. The precise mechanism and structure of the toxin are unclear. The two species responsible in the United States are Dermacentor andersoni (wood tick) and Dermacentor variabilis (dog tick). The bite of the tick is usually painless, but the victim later has difficulty walking, weakness, flaccid paralysis, slurried speech, and visual disturbances. The victim is usually a child, often with a history of recent outdoor activity. Treatment is removal of the offending tick before the paralysis has progressed too far. Any patient with ascending paralysis should be closely examined for the presence of a tick, especially on the head and back. Patients with a dermatologic erythema migrans rash or “target lesion” following a tick bite should be evaluated for Lyme disease and treated with doxycycline. Borrelia species known to cause Lyme disease are collectively known as Borrelia burgdorferi (see Chapter 126 for more details regarding tick bites and Lyme disease).

Several species of beetle, millipede, and caterpillar secrete irritating substances that cause severe burning pain, numbness, pustular contact dermatitis, edema, nausea, vomiting, and headache. Oropharyngeal exposure can cause mucosal edema and irritation. Deaths have rarely been reported. Treatment consists of washing the area thoroughly with soap and water and removing any spines or hairs present. Spines can be removed with adhesive tape or by applying white glue or facial peel. Locally applied ice bags and a paste of baking soda and water may be of benefit. Analgesics should be used as needed, and supportive therapy may be necessary for severe envenomation.

Centipedes can inflict bites that cause erythema and edema. Treatment is usually local soaks and the use of analgesics. Conenose bugs, or “kissing bugs,” may cause severe local and systemic allergic reactions. Treatment with antihistamines and supportive care, depending on the degree of reaction, are all that is necessary. Many other arthropods can cause local skin reactions and severe allergic reactions, depending on the individual’s sensitivity. Patients are treated symptomatically with local steroid creams, antihistamines, and other symptomatic supportive measures.

**VENOMOUS MARINE ANIMALS**

**Principles**

Almost 2000 species of animals found in the ocean are either venomous or poisonous to humans, and many can produce severe illness or fatalities. An estimated 40,000 to 50,000 marine envenomations occur annually. In recent years, the number of injuries caused by these animals has increased dramatically because of the greater number of scuba divers, snorkelers, surfers, and others engaging in water sports. These animals are not usually aggressive, and many are completely immobile. Most of the venomous marine animals injure humans with defensive or food-procuring devices. Most venomous marine animals in the United States are found along the California, Gulf of Mexico, and southern Atlantic coasts. These animals range in complexity from sponges to bony fishes and contain some of the most complex and toxic venoms known. Recently, populations of lionfish have been increasing in American coastal waters due to release of these predatory fish in nonindigenous waters.

**Venom Delivery**

In general, venomous marine animals are divided into three main classes according to the mechanism of venom delivery: bites, nematocysts, and stings.

**Bites**

Biting animals include several species of cephalopods, most often octopi. Although popular media portray a giant deadly creature that squeezes its victims to death, the most dangerous octopi are seldom larger than 20 cm. Several fatalities have been reported after a bite by the blue-ringed octopus, Hapalochlaena maculosa. Most victims are bitten on the upper extremity because they disturb this normally nonaggressive creature. The octopus has a pair of modified salivary glands that secrete venom into the wound produced by the animal’s beak. The venom contains a potent vasodilator and an inhibitor of neuromuscular transmission similar to tetrodotoxin. No known antivenom exists, and treatment is largely supportive, with respiratory support being the most important lifesaving intervention.

**Nematocysts**

The second type of venom mechanism is the nematocyst found in coelenterates (Cnidaria). This group of animals includes the Portuguese man-of-war, true jellyfish, fire corals, stinging hydroids, sea wasps, sea nettle, and anemones. Most of these organisms are sessile, but some are free floating. Because of their large numbers, this group accounts for the greatest number of envenomations by marine animals.

Many different types of nematocysts are known, but the basic mechanism is a “spring-loaded” venom gland that can, on mechanical or chemical stimulation, suddenly evert and discharge a structure that penetrates the prey and delivers the venom through a connecting tube. These nematocysts, found on the animal’s tentacles, can number in the hundreds of thousands. Tentacles can be up to 100 feet long in some giant species. Nematocysts can still function even if the animal is dead or if the tentacles are separated from the animal’s body. These stinging cells can remain active for weeks after an animal becomes beached. Often, not all nematocysts fire on initial contact but may discharge later during attempted rescue and treatment. Certain marine species have evolved methods of using ingested nematocysts for their own defense.

**Toxicity.** Nematocyst venom contains various peptides, phospholipase A, proteolytic enzymes, hemolytic enzymes, quaternary ammonium compounds, serotonin, and other toxic compounds. The venom of the coelenterates is antigenic, and allergic reactions are often seen. The severity of the envenomation is related to several factors. First, the severity of the injury is directly proportional to the number of nematocysts discharged. Second, the toxicity varies from species to species. It is unlikely that the victim or the treating physician will be able to identify the species from the appearance of the wound.

**Clinical Features**

Symptoms may range from simple isolated stinging to respiratory paralysis, cardiovascular collapse, and death. Therefore, the diagnosis must be made according to the clinical findings. The victim’s autopharmacologic response to the venom may turn a relatively minor envenomation into a fatal anaphylactic reaction. Any clinician who regularly treats this type of injury should become acquainted with the common species indigenous to their region.
introduces venom. Common examples of this type of animal are sea urchins, cone shells, bristle worms, crown-of-thorns starfish, stingrays, lionfish, weever fish, catfish, stonefish, rabbit fish, and zebra fish. Sea urchins, cone shells (*Conus californicus*), catfish, scorpion fish, and stingrays account for most of the venomous marine animal injuries in the United States.\(^6^5\)

**Sea Urchins.** Sea urchins belong to the Echinodermata phylum along with starfish and sea cucumbers. These animals produce injury and envenomation mostly through toxin-coated spines. These spines often break off and introduce calcareous material and debris into the wound, thereby potentiating infection. Symptoms most often include severe local burning, pain, and discoloration, but they may progress systemically in some patients. The degree of envenomation is usually related to the number of spines involved and the species of animal encountered.

**Cone Shells.** Cone shells are much more toxic than sea urchins, and some species have been responsible for fatalities in the Indo-Pacific region. The venom apparatus is a tubular gland that connects to several teeth at the end of a retractable proboscis. All envenomations reported have occurred in persons handling the shells. The venom contains several proteins, protein-carbohydrate complexes, and 3-indolyl derivatives that act mainly on skeletal muscle and cause variably spastic and flaccid paralysis. Symptoms may or may not include pain, depending on the species. Severe envenomation may cause diplopia, slurred speech, numbness, weakness, paralysis, and respiratory arrest. Onset and regression of symptoms may vary from minutes to days. No antivenom is available for cone shell envenomation. Airway control and supportive care are the mainstays of therapy for severe envenomations.

**Stingray.** The stingray is a member of the shark family. It is a broad, flat fish with a long, whiplike tail that may have one or more stingers with barbed ends. Stingrays vary in size from a few inches to several feet, and the stingers are proportional to the size of the fish. The stinger is encased in an integumentary sheath and contains venom glands. Stingrays bury themselves in the sand of shallow water, where they can be easily stepped on inadvertently.\(^6^6\) The sheath and stinger are often broken or left in the wound. The victim experiences an immediate, intense pain in the area of the wound, which may spread to the entire extremity. Systemic symptoms include salivation, nausea, vomiting, diarrhea, syncope, muscle cramps, fasciculations, dyspnea, cardiac dysrhythmias, and convulsions. The exact composition of the venom is unknown. Enzymes, proteins, serotonin, and a cholinergic substance have been identified, but the exact toxin responsible for most of the severe symptoms is yet to be isolated. The presence of foreign material may also impair healing and cause infection.

**Bony Fishes.** Bony fishes inflict their wounds through spines located on their fins. The spines and venom glands are encased in a sheath, and grooves along the spines act as channels for the venom. These fish injuries are typically encountered when the fish are stepped on in shallow water or handled by fishermen. The venom is made up of several classes of proteins, most of which are heat labile. The family Scorpaenidae includes three groups of species categorized by venom apparatus: zebra fish, scorpion fish, and stonefish. Zebra fish include the popular aquarium resident, the lionfish. Scorpion fish produce intense pain that can spread to the entire affected extremity within minutes. Stonefish envenomation may cause serious and even life-threatening systemic illness, but manifestations such as cardiac and respiratory symptoms can be prevented by early administration of the appropriate antivenom. Saltwater and freshwater catfish produce envenomation through contact with dorsal and pectoral spines.
Management

Much of the venom from marine animals can be neutralized at the scene, and most fatalities can be prevented. The most important step is to remove the victim from the water. Drownings after minimal envenomation may account for more fatalities than the end effects of severe envenomation. The patient should be questioned about the circumstances of the bite, allergies, and systemic symptoms. If a severe allergic reaction has occurred, the victim is treated for this emergency before the wound is addressed. The type of wound care largely varies according to the type of venom apparatus involved. All marine stings from either bony fish or stingrays are treated with immersion in hot (110°F) water for 30 to 90 minutes.67 This therapy usually improves pain within minutes, but supplemental analgesics may be needed. As with all wounds encountered in the ED, appropriate cleansing, débridement, and irrigation. Systemic signs and symptoms are treated as appropriate, with aggressive attention paid to the cardiac and respiratory systems.

Nematocysts

Nematocyst injuries are treated by first removing the nematocysts without allowing them to discharge. Tentacles are removed with a gloved hand or forceps. The remaining nematocysts are fixed by pouring vinegar (dilute acetic acid) over the wound area.67,70,71 For Physalia (man-of-war) stings, hot water may be useful or hot vinegar may be even better.72 Baking soda and alcohol have also been shown to be effective, and deactivation of nematocysts may be species specific. Fresh water is not used, because it may stimulate continued nematocyst discharge. Other methods include scraping off residual material with the use of a shaving cream or baking soda slurry. The affected area is then debrided and cleansed.

Hot water immersion may relieve pain. Most lifeguard stations in areas where coelenterate stings are common have the necessary materials for this regimen. Supportive pharmacologic therapy (eg, analgesics, antihistamines, and steroid creams) is indicated for all but the most trivial envenomation. Delayed cutaneous reactions may persist despite optimal therapy.

Early aggressive resuscitation offers the best chance of recovery from (Chironex fleckeri) stings. Box jellyfish antivenom is available in limited supply and may be life-saving.73,74 Delayed neutralizing effects of the antivenom may take up to 60 to 70 minutes to take full effect justifying prolonged cardiopulmonary resuscitation (CPR) and other resuscitation attempts in these patients.

Fish

Puncture injuries are treated by removing the spine or sting if possible. An x-ray film of the involved area is obtained because many spines and sheaths are radiopaque.75 Sea urchin spines usually break off in the wound; they are so fragile that removing them is difficult without the proper instruments. The stinger of the stingray should be removed with forceps, although these stingers with their sheaths have been known to penetrate body cavities and require surgery for removal. Although not usually present in the wound, the fish spines of bony fish should be removed with forceps. In all cases, the wound should be copiously irrigated. Most venoms injected through puncture wounds are heat labile. Significant analgesia can be achieved by submersion of the wound in hot (110°F) water for 30 to 90 minutes or until symptoms improve.69 A specific antivenom for stonefish envenomation is available in Australia.

Disposition

Patients envenomated by unknown or unfamiliar organisms should be observed for systemic signs and symptoms. Careful discharge instructions are provided to the patient, warning him or her to return for increasing pain, numbness, difficulty breathing, and signs of infection.

KEY CONCEPTS

- Snake venom causes neurotoxicity and hematotoxicity, but one usually predominates, depending on the species of snake.
- The amount of crotalid antivenom given depends on the grade of envenomation, from 0 (minimal or no sign of envenomation) to IV (severe envenomation). Antivenin recommended for grade II to IV snakebites. Children require the same amount of antivenom as adults.
- Pit vipers have a characteristic pit found midway between the eye and the nostril on both sides of the head.
- Arthropods such as hymenoptera account for more deaths from envenomation than snakes, usually as a result of allergic reactions.
- Black widow spider bites are neurotoxic causing severe pain and muscle spasms; brown recluse spider bites cause necrotizing skin wounds.
- Nematocyst (jellyfish) stings should be immediately neutralized with vinegar or hot water, and fish stings with hot water. Stings from venomous fish (such as, lionfish and sting rays) are treated with circulating hot water to denature the toxin.

CHAPTER 55: QUESTIONS & ANSWERS

55.1. Which of the following venomous snakes in the United States is a member of the neurotoxic Elapidae family?
A. Copperhead
B. Coral snake
C. Rattlesnake
D. Water moccasin

Answer: B. Pit vipers from the family Viperidae are the most prevalent venomous snakes in the United States. They are native to every state except Maine, Alaska, and Hawaii. They are classified into three main groups: true rattlesnakes (genus Crotalus), copperheads and water moccasins (genus Agkistrodon), and pygmy and Massasauga rattlesnakes (genus Sistrurus). Pit vipers account for 98% of all venomous snakebites in the United States. Other families include Colubridae, Hydrophiidae, Elapidae (to which the neurotoxic coral snake belongs), and Crotalidae.

55.2. A 30-year-old man complains of pain, burning, and swelling of his hand after gardening. Physical examination shows two puncture marks on his thenar eminence, as well as moderate localized swelling. When you inquire about it, he said that he did have some burning pain briefly while digging around in the ground by a bush, but he dismissed it as abrasions from sharp sticks. That was 2 hours ago. What should you do next?
A. Apply a constricting band to impede venous and arterial flow.
B. Discharge with instructions for rest, ice, immobilization, and use of oral antibiotics.
C. Give tetanus and clindamycin for prophylaxis.
D. Obtain baseline laboratory studies and observe the patient for increasing symptoms.
E. Test compartment pressure and prepare for fasciotomy.

Answer: D. The symptoms are typical for a pit viper snakebite. The most consistent symptom associated with pit viper bites is immediate burning pain in the area of the bite, whereas pain may be minimal with bites of Elapidae and other exotic snakes. Tetanus prophylaxis may be indicated, but antibiotics are not. Fasciotomy is rarely if ever indicated for snakebite. A constricting band may be useful for first aid in the field with certain neurotoxic snakes, but not in the emergency department (ED). Immobilization may be helpful, but ice and antibiotics are not.

55.3. A 43-year-old woman sustained a snakebite while in her garden. She was not able to secure the snake, but she remembered it to be colorful. She presents with ptosis, slurred speech, and nausea. What is true about the type of snake most likely involved in this case?
A. Death usually occurs from coagulopathies.
B. Eastern species are the most deadly.
C. The snake has a heat-sensitive organ between eyes and nostrils on both sides of the head.
D. The snake has a triangle-shaped head.
E. The snake has elliptical pupils.

Answer: B. This woman sustained a bite from a coral snake. All of the above except B are related to pit vipers. The coral snake can be differentiated from the king snake by two characteristics: the nose of the coral snake is black, and the red and yellow bands are adjacent on the coral snake. Eastern coral snake is considered deadly as opposed to its western relative. There are no records of fatalities caused by the western species. Ptoxis is common and often the first outward sign of envenomation. Other signs and symptoms include vertigo, paresthesias, fasciculations, slurred speech, drowsiness, dysphagia, increased salivation, nausea, and proximal muscle weakness.

55.4. Which of the following is true about antivenom?
A. Antivenom may reverse all the symptoms of envenomation.
B. Antivenom should be administered around the wound.
C. Even mild envenomations require antivenom.
D. Exotic snakebites require only antivenom if neurologic symptoms are present.
E. Pregnancy is a contraindication to receive antivenom.

Answer: E. Most copperhead bites do not require antivenom. Some toxicologists will administer antivenom if swelling is severe and may cause long-term disability. Copperhead bites generally cause a moderate amount of swelling that may peak 24 to 36 hours after the bite. All venomous snakebites should be observed for at least 12 hours if signs of envenomation are present. If systemic signs develop or the patient develops a coagulopathy, antivenom may be indicated.

55.5. A 28-year-old man presents with a copperhead snakebite that occurred 1 hour ago. He complains of pain and moderate swelling of his right hand and wrist. He has no systemic symptoms and has a pulse of 92. His initial coagulation studies are normal. What should be done?
A. Admit for observation and antivenom
B. Discharge with elevation, ice, and pain medications
C. Give antivenom if swelling spreads to forearm
D. Immediate antivenom 4 vials intravenously
E. Observe 12 hours for signs of increasing envenomation

Answer: D. Immediate antivenom should be given, and the patient should be observed for at least 12 hours. If signs of envenomation are present, antivenom should be administered.

55.6. Which of the following patients is most likely to be the first discharged home safely?
A. A pregnant woman with black widow envenomation
B. A 5-year-old child with a scorpion sting 1 hour before arrival
C. A 55-year-old man with hypertension and coronary artery disease with black widow envenomation
D. An 8-year-old with a coral snake bite
E. An 18-year-old with an unknown snake bite 8 hours before arrival

Answer: E. A scorpion sting in a child should be observed for at least 6 hours. Symptomatic children with stings should be admitted. Most venomous snakes will show signs of envenomation with 6 hours. If this patient is asymptomatic, it is likely that the snake was nonvenomous or this was a “dry bite.” All children with envenomation and coral snake bites should be admitted for observation. Pregnant patients and those with coexisting medical problems should be admitted after black widow envenomations.

55.7. While walking in shallow water, a patient accidentally steps on a stonefish. Which of the following is not indicated?
A. Irrigating the wound with vinegar
B. Obtaining radiographs for retained foreign body
C. Observing for cardiovascular and respiratory symptoms

Answer: B. Stonefish do not have a spine, and therefore radiographs are not indicated. Other treatment includes cleansing the wound and monitoring for cardiovascular and respiratory symptoms.
D. Removing the spine with forceps
E. Using hot water to relieve the pain

**Answer:** A. Stonefish, a type of bony fish, may cause serious cardiac and respiratory symptoms, which can be prevented by early administration of the appropriate antivenom. The fish spines of bony fish should be removed with forceps because they are thick and less likely to break off at the skin (like a bee stinger). In all cases, the wound should be copiously irrigated. Vinegar has been shown to be useful for some types of nematocyst injuries from jellyfish. Significant analgesia is achieved by submersion of the wound in hot water for 30 to 90 minutes or until improvement.

55.8. A patient presents with a necrotic lesion on her midthigh that started as a bleb while she was working in her garden 3 days ago. The wound has grown gravitationally. Her blood pressure is 110/80 mm Hg, respiratory rate 16 rpm, heart rate 110 bpm, and temperature 38.3°C. You suspect an envenomation of which of the following?
A. *Centruroides exilicauda*
B. *Hapalochlaena maculosa*
C. *Haplopelma lividum*
D. *Latrodectus mactans*
E. *Loxosceles reclusa*

**Answer:** E. The cobalt blue tarantula, *Haplopelma lividum*, is an aggressive spider with toxic venom. The black widow spider is *Latrodectus mactans, Centruroides exilicauda*, which is found in Arizona, is a particularly dangerous kind of scorpion. The blue-ringed octopus is *Hapalochlaena maculosa*. The brown recluse spider, *Loxosceles reclusa*, causes an initial white area of vasoconstriction at the site of the bite within 3 or 4 hours. A bleb then forms in the center of this area, and an erythematous ring arises on the periphery. The lesion at this stage resembles a bull’s-eye. The bleb darkens, necroses during the next several hours to days, and continues to spread slowly and gravitationally.
PRINCIPLES

Background

Thermal burns are common injuries seen and managed in the emergency department (ED). In most cases, burns are relatively small in size and superficial in depth and can be managed entirely by the emergency clinician without the need for emergent consultation or admission. Accurate assessment of burn size and depth followed by meticulous local wound care is all that is needed in most cases. On the other hand, early management of the airway, breathing, and circulation are essential in the treatment of major burns. Emergency escharotomy may also be required sometimes, especially with circumferential burns of the extremities, thorax, and neck.

The ability of the skin to regenerate is largely dependent on the depth of injury because regeneration occurs mostly from underlying dermal skin appendages, such as the hair follicles and sebaceous glands. Cooling of the burns as well as prevention of wound desiccation and infection will help prevent conversion of the burns from partial (second degree) to full thickness (third degree). Unlike mechanical injuries, in which the maximal extent of damage occurs immediately after injury, thermal burns are dynamic and tend to progress over time. As a result, it may be difficult to accurately assess burn depth and be able to predict the potential for spontaneous healing without the need for burn eschar excision and skin grafting during the initial ED assessment.

Although burn depth may be obvious in very superficial and very deep burns respectively, in many cases close follow-up and frequent reassessments may be required to determine the appropriate therapeutic plan. Consultation with a burn specialist is recommended with obviously deep burns and when burn depth is indeterminate.

Epidemiology

Although the number of burns in the United States has appeared to be decreasing, a recent study from England suggests that this trend may be reversing with an increase in total number of burns. The overall survival rate from burns in the United States is over 96% with 3400 deaths per year. Between the years 2003 to 2012 the case fatality rate from burns decreased 25% to 35%. Most burns occur in men in the working years of life. Although scalds are the most common etiology of burns in children younger than 5 years old, burns due to exposure to fire or flame predominate in all other age groups.

Most burns are relatively small in size with only 2% covering 40% total body surface area (TBSA) or more. Currently, the burn size associated with a 50% case fatality (LA-50) is between 60% and 70% TBSA. The hospital length of stay can be estimated and is roughly 1 day per percent TBSA burned.

Anatomy and Physiology

The skin is the largest organ of the body and is composed of three main layers: the epidermis, the dermis, and the subcutaneous layers. The epidermis provides a waterproofing and bacteria-proofing layer, whereas the dermis (along with the subcutaneous layer) gives the skin its toughness and durability. The dermis and subcutaneous layers are also important sources of stem cells that help regenerate the epidermis after thermal injury.

The main function of the skin is to serve as a barrier between the internal and external environments minimizing fluid losses and microbial invasion. Other important functions of the skin include thermoregulation, sensory detection, and immune surveillance. When large portions of the skin are lost or damaged, there is a risk of hypovolemic shock and sepsis, and complete loss of the skin is incompatible with life.

Pathophysiology of Burns

Burns are the result of exposure of the skin, to energy in the form of heat. The degree of injury is dependent on the temperature and duration of exposure as well as the structure of the skin. The skin in the very young and elderly is relatively thin; therefore, they are more prone to the development of deep burns. Temperatures below 44°C are generally well tolerated and do not cause cell death or injury even after prolonged periods of exposure. When the temperature rises, there is damage to the cells ultimately leading to cell death. Exposure of cells to supra-physiological temperatures results in progressive denaturation or unfolding of protein molecules with most proteins denatured at 60°C. The lipid bilayer and membrane-bound adenosine triphosphates are especially vulnerable to thermal denaturation leading to disruption of the cellular membrane and subsequent cellular necrosis. In addition to classical cellular necrosis, cell death may also occur as a result of apoptosis and necroptosis. Cellular necrosis (also known as oncosis) is a result of depletion of the cell’s energy stores and loss of integrity of the cellular membrane with subsequent cellular swelling leading to bursting of the cell with significant associated inflammation. In contrast, apoptosis is a highly programmed active process characterized by shrinking of the cell and its organelles, DNA fragmentation, and budding without cellular swelling ultimately leading to cell death with minimal inflammation. Apoptosis is the result of activation of caspase proteases that ultimately are the executors of cell death. A third mechanism of cell death that has recently been reported is necroptosis in which the cells also swell and burst.

However, unlike classical necrosis, necroptosis is an active programmed process that requires the formation of an intracellular complex, which includes receptor-interacting protein 3 (RIP-3). Autophagy (a pathway that conserves energy by recycling intracellular macromolecular waste) may also play a role in burn injury progression. The importance of these findings is that it paves the way for the development of potential therapies aimed at preventing necroptosis or apoptosis.

The pathophysiology of burns in many ways resembles that of myocardial infarction, stroke, and traumatic brain injury. In all of these cases, a large number of cells are irreversibly damaged by exposure to the most extreme injury conditions, whereas the cells in the surrounding area are exposed to lesser insults putting them at risk of death due to stasis or a reduction in blood flow. The
classical three zones of burn injury originally described by Jackson include the central zone of irreversible necrosis, the intermediate and potentially reversible zone of stasis, and the outermost reversible zone of inflammation.10 Thermal injury sets into motion a cascade of events, which includes inflammation, compromised perfusion, oxidative stress, and recurring cycles of ischemia reperfusion.11 These processes result in the release of a large number of toxic cytokines and mediators, as well as free oxygen and nitrogen radicals leading to additional injury. For example, free radicals damage vital proteins, lipids, and DNA leading to lipid peroxidation and disruption of the cellular membrane. Occlusion of the dermal microcirculation by red and white blood cells followed by the formation of microthrombi further reduces perfusion to the injured skin. Additionally increases in capillary permeability lead to edema formation, which further compromises local blood flow.

Burn injuries are also characterized by a catabolic state with up to a threefold increase in the metabolic rate often necessitating enteral or parenteral nutrition. In addition to adrenergic stress, burn hypermetabolism may be due in part to uncoupling of oxidative phosphorylation in the mitochondria.12 Nonspecific down regulation of the immune system also occurs due to defects in both cell mediated and humoral pathways possibly as a result of the release of mediators, such as interleukin-12 (IL-12) and IL-17.13

Smoke inhalation-associated lung injury occurs in approximately 2% of burn victims with <20% TBSA burns and in 14% of burns with 80% to 99% TBSA and contributes greatly to mortality.14 Although more common with large burns, inhalation injury can exist with or without cutaneous burns; however, its presence is associated with a more than threefold increase in mortality.14 Anatomically, injuries from smoke inhalation may involve direct heat injury to the upper airway, chemical injury to the lower airway, and systemic toxicity such as with inhalation of carbon monoxide or cyanide. Unless exposed to steam, the heat dissipating properties of the upper airway generally restrict direct thermal injury to the supraglottic structures. Lower airway and intrathoracic injury is generally the result of exposure to various chemicals contained in the smoke.

A large variety of toxic substances may be released with burning materials, such as rubber and plastic including sulfur dioxide, cyanide, nitrogen dioxide, ammonia, and chlorine, as well as toxic aldehydes. These substance damage epithelial and endothelial cells of the airways and their blood vessels leading to the formation of pseudomembranes or airway casts consisting of cellular debris, fibrin, and mucin that obstruct the airways and cause significant mismatches in ventilation and perfusion (V/Q). Increases in inflammatory mediators and reactive oxygen and nitrogen species lead to further impairments in blood flow worsening V/Q mismatch. Air trapping from the formation of ball valve obstructions of the airway may also lead to regional barotrauma further injuring the lungs. Mucociliary transport is also impaired leading to a reduction in bacterial clearance and risk of infection. Loss of surfactant can lead to alveolar collapse and atelectasis resulting in further impairment in ventilation and oxygenation. The toxic effects of carbon monoxide and cyanide are discussed in Chapter 153.

### CLINICAL FEATURES

#### Classification and Diagnosis of Burns

The prognosis and management of thermal burns are dependent on the depth and surface area of the burn, emphasizing the need for accurate estimates of burn depth and size. Unfortunately, both estimations can be difficult and inaccurate. Although clinical examination is most commonly used to determine burn depth (even when performed by a burn specialist), its accuracy is only 50% to 75%.15 A large number of modalities have been evaluated to improve the accuracy of clinical estimation of which only laser Doppler imaging of dermal perfusion is used.16 However, its use has been limited mostly to burn centers and research facilities. The dynamic nature of burn injuries and their tendency to progress over time reemphasizes the need for close monitoring and follow-up.

The depth of burns has traditionally been classified as first, second, or third degree based on the degree of involvement of the dermis (none, partial, and complete, respectively). Although first-degree burns almost always heal within 1 week without any scarring or sequelae, third degree burns generally require more than 3 weeks to heal and result in significant scarring (although this dogma has recently been challenged).17 As a result, most third degree burns (unless very small, usually less than 1 cm²) will require surgical excision and skin grafting. Because the dermis is relatively thick (up to 1 to 3 mm) and the ability of second degree burns to heal spontaneously without much scarring is dependent on how many dermal appendages survive, second degree burns have been further classified as superficial partial (limited to the upper or papillary dermis) and deep partial thickness burns (including the deeper reticular dermis). In contrast, third degree burns that involve the entire thickness of the dermis are called full thickness. Clinical findings that help with estimating the burn depth include color, presence of blisters, skin pliability, capillary refill, and sensitivity to touch or needle prick (Table 56.1). Typical examples of the appearance of different burn depths are presented in Figures 56.1 to 56.3.

The percentage TBSA burned predicts mortality and helps determine the amount of fluid resuscitation required. The Baux score is the sum of the patient’s age and the percentage of TBSA burned.18 In the original article, the Baux score that predicted 100% mortality was 100. A more recent study found that a Baux score of 160 predicted 100% mortality, and a Baux score of 109.6 predicted 50% mortality (95% confidence interval), which is a

CHAPTER 56  Thermal Burns

lead to excessive intravenous fluid administration that can result in compartment syndromes and acute respiratory distress syndrome (ARDS). For large burns, Wallace’s “rule of nines” is often used to estimate burn size. The “rule of nines” method divides the body into areas that approximate 9% of the TBSA—the head and neck, each upper extremity, the anterior or posterior surfaces of each of the lower extremities, and half of the anterior or posterior surfaces of the trunk (Figure 56.4). With children, the Lund-Browder chart should be used that adjusts for age related differences in the distribution of body parts and sizes (Figure 56.5). For small burns, the surface of the patient’s palm (including the palmer surface of the fingers) can be used to estimate 1% of the TBSA. A number of methods have been developed to increase the accuracy of burn size estimation. Mobile applications and computer software help improve burn size estimation. Burn severity has also been classified as mild, moderate, and severe based on a combination of age, depth, and size (Table 56.2).

DIFFERENTIAL DIAGNOSES

The diagnosis and etiology of burns is generally straightforward. A number of other diseases may sometimes masquerade as burns, such as epidermal necrolysis and pemphigus. Epidermal necrolysis is a spectrum of life-threatening mucocutaneous eruptions, including Steven-Johnson syndrome and toxic epidermal necrolysis characterized by diffuse erythema and sloughing of large areas of the skin, usually caused by a medication or infection.
The consequences and management of epidermal necrolysis are very similar to those of large burns. Pemphigus includes a spectrum of autoimmune bullous diseases characterized by the formation of multiple blisters in the skin and mucous membranes. The blisters generally appear in the mucous membranes first followed by the skin. When left untreated, they may become generalized. Inciting factors, such as medications, infections, and stress, may be identified. Child or elderly abuse must always be considered, especially when the history and pattern of burns are inconsistent with the physical findings.

### Diagnosis

Routine laboratory testing is generally of little value in evaluating and managing patients with burns in the ED. Patients with suspected inhalation injury should have a chest radiograph and blood gas determination, including carbon monoxide levels. In patients with little or minimal symptoms or signs of inhalation injury, pulse oximetry and noninvasive determinations of carbon monoxide may be used. Patients with large burns requiring an admission should have baseline laboratory testing, including a complete blood count, basic metabolic panel, blood type and cross, and coagulation studies, which may all become impaired in patients with large burns.

### Management

#### Initial First Aid

Patients should be removed from the source of injury and any garments and jewelry removed from the affected areas. Burns should be cooled with room temperature water. Direct exposure to ice or iced water should be avoided because it may result in frostbite. In patients with large burns careful monitoring of core body temperature is recommended to avoid hypothermia. Although the subject of debate, in general blisters should be left intact. In the ED most blisters should be left intact; however, very large or tense blisters, as well as those located over joints, should probably be ruptured to ease local wound care. The burns should be covered with a clean dressing to minimize further trauma and reduce pain associated with air currents.

During transport to the ED patients with large burns (greater than 20% in adults and greater than 10% in children) should have two large bore intravenous catheters placed and fluid resuscitation should be initiated (see later for more details on fluid resuscitation). Patients should be placed on supplemental oxygen to maintain oxygen saturation greater than 92%. Pain management using intravenous doses of an opioid is also recommended as per local emergency medical service (EMS) protocols in hemodynamically stable patients (see later for more details on pain management).

#### Airway Management

One of the most critical decisions in managing burn victims is the need for and optimal timing of endotracheal intubation because injury to the upper airway may result in massive swelling of the tongue, epiglottis, and aryepiglottic folds. In some cases (such as, in the presence of significant oropharyngeal swelling, stridor, and respiratory distress), the decision to intubate is obvious and straightforward. In other cases, airway swelling may develop more gradually over several hours as fluid resuscitation proceeds. Clinical signs such as facial burns, hoarseness, drooling, carbonaceous sputum, and singed nasal hairs certainly should raise the probability of inhalation injury. However, they are often unreliable and poor predictors of injury. A recent prospective study of 100 burn patients with suspected inhalation injury that were evaluated by fiberoptic bronchoscopy found that 21% had no evidence of upper airway involvement and 39% had no lower airway pathology. In contrast, 38% of patients with documented inhalation injury did not have singed nasal hair. Traditionally emergency clinicians have been encouraged to secure the airway as early as possible, even prophylactically, prior to the onset of airway obstruction. When in doubt, early intubation is encouraged; however, the presence of neck or facial burns alone should not be an indication for intubation. Recently there have been concerns that overly aggressive airway management may be detrimental to patients. Inappropriate intubation and mechanical ventilation may lead to the ARDS possibly due to the release of inflammatory mediators.

mediators. Ventilator-associated pneumonia is also seen in up to 30% of ventilated burn patients. A study of 1029 intubated burn patients found that 17% underwent extubation within hours and another 49% within 1 day of admission without the need for reintubation, suggesting that tracheal intubation was unnecessary. Another study found that inhalation injury could not be confirmed in more than half of the burned patients that were intubated. The best way to confirm inhalation injury and the need for endotracheal intubation is by directly visualizing the upper airways with fiberoptic, video, or direct laryngoscopy using topical anesthesia supplanted with mild to moderate sedation when necessary. The presence of significant edema or soot in the supraglottic region necessitates immediate intubation (Figure 56.6). When necessary, small doses (10 to 20 mg) of intravenous ketamine can be used to sedate the patient without compromising their ability to control the airway. An intravenous dose of glycopyrrolate (0.1 to 0.2 mg) may also be considered prior to laryngoscopy to reduce secretions. Laryngoscopy may also be repeated if the clinical condition changes. Rapid sequence induction should be avoided unless direct visualization confirms that tracheal intubation will be relatively easy. Rarely, a surgical airway is required when it is not possible to endotracheally intubate the patient. Awake intubation with generous amounts of topical anesthetics with or without supplemental sedation should be used when a difficult airway is suspected.

Breathing Management: Recognition and Management of Inhalation Injury

A history of exposure to smoke in a closed space should always raise the suspicion for smoke inhalation. Physical findings may include facial burns, singed nasal hair, hoarseness, drooling, stridor, and carbonaceous sputum. However, clinical signs may be unreliable. Although the chest radiograph and CT scans of the thorax may be helpful in some cases, direct visualization of the upper airways remains the best method for confirming the presence of inhalation injury. All patients with suspected inhalation injury should receive supplemental humidified oxygen to maintain oxygen saturation above 92%. Inhaled beta-agonists should be administered to reduce bronchoconstriction associated with inhalation injury. Carbon monoxide levels should be measured using CO-oximetry or noninvasive bedside devices. Cyanide toxicity should be suspected in patients injured in a closed space, especially with combustion of plastics and in the presence of lactic acidosis.

Endotracheal intubation and mechanical ventilation are indicated with persistent hypoxemia despite supplemental oxygen. Other indications for intubation and mechanical ventilation are included in Box 56.1. The best method of ventilation in patients with inhalation injury is subject to debate. A large randomized trial of patients requiring mechanical ventilation demonstrated lower mortality with lower tidal volumes (6 mL/kg of predicted weight). Maintaining airway plateau pressures below 35 mm Hg is also desirable to avoid further injury from overinflation of the poorly aerated lungs. This may lead to hypercapnia (permissive hypercapnia), which should be tolerated as long as the PCO2 remains below 60 mm Hg and the pH remains above 7.2 and is also desirable to avoid further injury from overinflation of the poorly aerated lungs. This may lead to hypercapnia (permissive hypercapnia), which should be tolerated as long as the PCO2 remains below 60 mm Hg and the pH remains above 7.2. There is no hemodynamic instability. Addition of positive end-expiratory pressure (PEEP) may increase residual capacity and improve oxygenation. Suggested initial ventilator settings are presented in Table 56.3. Some studies suggest that high frequency percussive ventilation (HFHV) may improve oxygenation in patients with inhalation injury when traditional methods (such as, assist control) are ineffective. Prone positioning of the patient may also be considered in hypoxic patients. Noninvasive ventilation may be considered in awake, cooperative, spontaneously breathing, hemodynamically stable patients who can maintain their airway.

Patients with smoke inhalation are at risk of developing pneumonia. Simple strategies such as elevating the head of the bed, frequent position changes, and good oral care should be used. However, prophylactic antibiotics do not reduce the risk of ventilator-associated pneumonia.

A number of strategies have been used to help reduce the copious secretions that tend to obstruct the airways. Bronchoscopic lavage may be used to remove airway debris and secretions that impede ventilation and enhance the inflammatory response. Because intra-airway coagulation and fibrin deposition play a significant role in the pathology of inhalation injury, anticoagulants have also been evaluated. A recent systematic review of preclinical
and clinical studies concluded that inhaled anticoagulant regimens improved survival and decreased mortality without altering systemic markers of clotting and anticoagulation. An aerosolized combination of an oxygen free radical scavenger and mucolytic, N-acetylcysteine (the antidote for acetaminophen toxicity), with heparin has been shown to improve outcomes in some but not all studies. Its use, as well as bronchial lavage, should probably be limited to the burn unit.

**Circulation Management and Fluid Resuscitation**

Burn injuries result in significant fluids losses and fluid shifts due to loss of the epidermal barrier and an increase in capillary permeability respectively. Leakage of plasma proteins into the interstitial space during the early phases of a burn increases its oncotic pressure, further contributing to fluid shifts and tissue edema. As a result, a major focus of burn care is fluid resuscitation to restore tissue perfusion and prevent hypovolemic shock. Intravenous fluid resuscitation through large bore intravenous cannulas is based entirely on lactated Ringer solution (see Table 56.4). Although these formulas are used as a general starting point, frequent readjustments based on patient response (vital signs, mental status, and hourly urine output) are required to avoid both over and under resuscitation. Of all parameters, urine output is most accurate in assessing the clinical response to fluid resuscitation with limited evidence of increased benefit with utilization of more invasive hemodynamic monitoring. Overly aggressive fluid resuscitation has been coined "fluid creep" and can have devastating results, including worsening local tissue edema with burn conversion, extremity compartment syndrome, abdominal compartment syndrome, and pulmonary edema. The Parkland formula is the most common method used to calculate fluid requirements over the first 24 hours after injury and is based entirely on lactated Ringer solution (see Table 56.4). Half of the fluids are given within the first 8 hours from injury.

(vessels, nerves, muscle) leading to a compartment syndrome. Similarly, an eschar involving the thorax may impede ventilation. When this occurs, emergent release of the tissue pressure by making an incision through the eschar (escharotomy) is required to prevent tissue necrosis and hypoventilation respectively. Because the eschar is composed of necrotic tissue, escharotomy is generally associated with little pain or blood loss. The amount of blood loss can be further minimized by using electric cautery. To be effective, the incisions should be down to the subcutaneous level, allowing the stiff eschar shell to split open. The incisions should also be slightly extended into normal tissue both proximally and distally. Along the extremities, the incisions are made over the medial and lateral aspects to avoid damage to underlying vital structures. With hand burns the incisions may need to be extended into the fingers. The proper placement of escharotomy incisions over the chest are displayed in Figure 56.7. The absence of distal pulses as well as distal Doppler and pulse oximetry signals indicate that an escharotomy is required. However, their presence should not be used to exclude the need for emergent escharotomy. Increased pain (especially with passive motion), pallor, weakness, and sensory loss all may be signs of impending compartment syndrome.

**Local Wound Therapies**

With most burn victims, care focuses on local wound therapies aimed at protecting the burn from further injury and infection and maintaining a moist wound environment that is most conducive to healing. First-degree burns do not require any local treatment. However, topical application of a nonsteroidal anti-inflammatory agent or aloe vera may reduce pain. In addition, systemic administration of an analgesic, such as acetaminophen or a nonsteroidal anti-inflammatory drugs (NSAIDs), should be considered.

After cleaning the burn with soap and water, large or tense blisters should either be aspirated with a needle or de-roofed and any nonadherent necrotic tissue should be gently removed. If the burn is very deep or involves a large area, the patient will require admission, preferably to a burn unit. In this case, local wound therapy should generally be performed in the burn unit. If the patient is to be transferred, the burns should be covered with a clean, nonadherent dressing. Small (<1% TBSA) full-thickness burns that are being referred to a burn specialist within 48 hours can be covered with an antimicrobial agent (such as, a triple antibiotic) and an outer absorptive dressing.

Management of partial thickness burns is subject to considerable debate as evidenced by the large number of natural and synthetic agents and dressings available (Table 56.5). The two methods of local treatment include a topical antibiotic ointment or cream together with a nonadherent yet absorptive dressings or one of many occlusive wound dressings (see Table 56.5). Ointments are preferred over creams because they are better tolerated, maintain a moist wound environment, and do not adhere to overlying dressings. With facial burns or over areas that are difficult to dress, application of a topical antibacterial ointment is recommended. Silver sulfadiazine cream has a wide antibacterial and antifungal spectrum and should be considered in heavily contaminated or infected burns. A systematic review of 30 randomized controlled trials found that silver sulfadiazine was consistently associated with poorer healing outcomes than biosynthetic (skin substitute) dressings, silver-containing dressings, and silicone-coated dressings. Therefore, silver sulfadiazine is no longer recommended for most burns. A recent randomized controlled trial found that even burns treated with a petrolatum-impregnated gauze without an antibacterial agent healed slightly faster that silver sulfadiazine treated wounds. Use of topical agents is also generally preferred for heavily exuding burns. When topical agents are used, they should be applied once or twice daily after washing the burn wound with mild soap and water while removing any nonadherent debris.

An alternative to topical antimicrobials, especially in burns without heavy exudation, is one of a number of commercially available occlusive dressings (see Table 56.5). Although generally more expensive than topical agents, occlusive dressings require less frequent dressing changes and are associated with less pain. Therefore, occlusive dressings may also be cost effective when compared to less expensive topical agents. A large number of materials such as foams, alginates, silicones, hydrocolloids, and hydrogels (with or without antimicrobial agents, such as very low concentrations of silver) have been studied. A systematic review of burn dressings in children with partial thickness burns found that membranous dressings, such as Biobrane and amnion membrane, improved healing, shortened hospital stay, and reduced pain compared with an antibacterial impregnated gauze. However, the use of these biological dressings is best limited to a burn specialist. Our recommendation is a silicone-coated foam dressing impregnated with silver (Mepilex Ag) that is absorptive, conforms to bodily contours, and is easy to remove without causing additional injury to the tissues. With most of the occlusive dressings, the dressing may be left in place for approximately 1 week unless obviously saturated or malodorous. Burns on the extremities should be elevated to reduce swelling and care should be taken to avoid tight compressive dressings.

A number of novel burn therapies have been investigated in preclinical and clinical studies but are not yet recommended in emergency settings. A systematic review of preclinical studies...

Pain Management

Due to the direct stimulation of nociceptors in the skin and the transmission of painful neural impulses via A-delta and C-fibers, most burns are very painful. However, the pain in burn victims is often undertreated.53 Routine monitoring of pain severity and the use of pain management protocols have been shown to improve pain management.62 Although pharmacological agents are the cornerstone of burn pain management, non-pharmacological methods (such as, cooling of the burn, covering the burn with a dressing) and cognitive-behavioral therapy (such as, relaxation and distraction) should be considered.64 Most national guidelines for the management of burn-associated pain include acetaminophen (500 mg every 6 hours) or NSAIDs (such as ibuprofen 400 mg every 8 hours) for mild to moderate pain and opioids (such as, fentanyl at 1 to 2 mcg/kg or morphine at 0.1 mg/kg) for more severe pain.65 The addition of an anxiolytic, such as midazolam or lorazepam, may be more effective than an opioid alone. A systematic review of four experimental trials involving 67 patients found that intravenous ketamine (0.1 to 2 mg/kg) showed some efficacy as an analgesic for burn injuries, with a reduction in secondary hyperalgesia when compared with opioid analgesia alone. Combination therapy with ketamine and morphine also resulted in the abolishment of the wind-up pain phenomena (the perceived increase in pain over time).66 Furthermore, the side-effect profile seemed to be similar to opioids alone. Despite initial studies suggesting that intravenous lidocaine may be effective in treating severe burn pain, the current literature does not support its use.67 The anticonvulsants gabapentin and pregabalin (which inhibit presynaptic N-methyl-d-aspartate [NMDA] receptors) may also be considered in burn patients with severe pain despite traditional therapies.68 However, these therapies are not useful in the immediate post burn period.

DISPOSITION

Most superficial and small burns can be managed in the ED by an emergency clinician with close follow-up by a physician comfortable handling burns (usually a burn specialist) within the next 3 to 5 days. Patients with large or deep burns, burns involving sensitive areas, and those with significant comorbidities and trauma should be admitted. Criteria for referral to a burn center are presented in Box 56.2.68

BOX 56.2
Criteria for Referral to a Burn Center

Partial thickness burns greater than 10% TBSA
Burns that involve the face, hands, genitalia, perineum, or major joints
Third degree burns in any age group
Electrical burns, including lightning injury (see Chapter 134)
Chemical burns
Inhalation injury
Burn injury in patients with preexisting medical disorders that could complicate management, prolong recovery, or affect mortality
Any patient with burns and concomitant trauma (such as, fractures) in which the burn injury poses the greatest risk of morbidity or mortality
Burned children in hospitals without qualified personnel or equipment for the care of children
Burn injury in patients who will require special social, emotional, or rehabilitative intervention

TBSA, Total body surface area.
CHAPTER 56  Thermal Burns

The references for this chapter can be found online by accessing the accompanying Expert Consult website.

**KEY CONCEPTS**

- After carefully removing the patient from the source of injury, burns should be cooled with room temperature water while avoiding hypothermia in patients with very large burns.
- Clinical signs such as facial burns, hoarseness, drooling, carbonaceous sputum, and singed nasal hairs certainly should raise the probability of inhalation injury; however, they are often unreliable and poor predictors of injury severity.
- The best way to confirm inhalation injury and the need for endotracheal intubation is by directly visualizing the upper airways with fiberoptic, video or direct laryngoscopy using topical anesthesia supplaned with mild to moderate sedation when necessary. The presence of significant edema or soot in the supraglottic region necessitates immediate intubation.
- Supplemental oxygen should be given in patients with suspected inhalation injury and determination of carbon monoxide levels should be performed.
- Fluid management to support vital organ perfusion and adequate urine output using crystalloids by the Parkland formula or modified Brooke formula should be administered as recommended by the American Burn Association.
- Adequate pain relief for larger burns may be accomplished using frequent intravenous titration with opioids supplemented with sub-dissociative doses of ketamine.
- While patients with large (>20% for adults and >10% for children and the elderly) or deep burns will require admission to a burn center, most patients presenting to the ED will have small and superficial burns that can be managed by over-the-counter topical antibiotic ointments (silver sulfadiazine is no longer recommended except for highly contaminated or infected wounds), or with one of many commercially available burn dressings.

CHAPTER 56: QUESTIONS & ANSWERS

56.1. A 30-year-old man presents with a burn to both anterior aspects of his forearms after being burned by a radiator. He has severe pain and has deep (reticular) dermis extension of the burn. You call the consultant and describe the burn as which of the following?
A. First-degree burn of 4.5% body surface area
B. Second-degree superficial burn of 9% body surface area
C. Second-degree deep burn of 4.5% body surface area
D. Third-degree burn of 2.5% body surface area
E. Fourth-degree burn of 9% body surface area

Answer: C. Deep second-degree burns extend through the epidermis into the deep (reticular) dermis. Body surface area is determined by the rule of nines. Nine percent for each upper extremity means that the forearm is approximately one fourth of 9%. Two forearms burns are half of 9%. Second-degree burns are often more painful than third-degree burns, in which all of the nerve endings are destroyed.

56.2. A 3-year-old boy presents with circumferential burns involving both upper extremities, including his hands, from pulling a boiling pot of water off the stove. The burns are mixed second-degree and third-degree burns. Which of the following best describes the body surface area burned and the most appropriate disposition?
A. 9% and admit to pediatrics with surgery consultation
B. 9% and transfer to burn unit
C. 18% and transfer to burn unit
D. 18% and admit to pediatric surgery
E. 20% and admit to pediatric intensive care unit

Answer: C. Children with burns over 10% total body surface area (TBSA) should be transferred to a burn unit. In addition, hand burns should be treated at a burn unit. Circumferential burns are not consistent with a splash injury, and child abuse should be suspected and reported.

56.3. A 55-year-old, 80-kg man presents with second-degree burns of both his legs, front torso, and groin. What is the initial fluid resuscitation according to the Parkland formula?
A. 500 mL lactated Ringer solution in the first 4 hours
B. 1100 mL normal saline in the first hour
C. 1100 mL of lactated Ringer solution in the first hour
D. 2400 mL normal saline in the first hour
E. 4200 mL lactated Ringer solution in the first 4 hours

Answer: C. The amount of lactated Ringer solution required for the first hour can be rapidly estimated with the Parkland formula by multiplying the estimated total body surface area (TBSA) of the second- and third-degree burn (55%) by body weight in kilograms (80 kg) and dividing by 4.

56.4. A 25-year-old woman presents with a second-degree burn to her right forearm after a grilling accident. You note areas of gray discoloration with decreased blanching in the erythematous region of the burn. In addition to irrigation, débridement, and dressing with a nonadherent dressing, which of the following would be the most appropriate treatment?
A. Apply silver sulfadiazine and follow-up with plastic surgery in 1 week
B. Calculate the Parkland formula and administer fluids before discharge
C. Educate the patient about daily dressing changes and have her follow-up with plastic surgery in 24 to 48 hours
D. Immerse her forearm in ice water for pain control
E. Unroof soft blisters and have the patient follow-up with her primary care physician in 1 week

Answer: C. The distinction between superficial and deep second-degree burns is important in that deep second-degree burns often do not heal within 2 or 3 weeks and may result in severe scarring and contractures, especially in children. As a result, deep second-degree burns that do not heal within 21 days may require excision and skin grafting to minimize scarring. Deep second-degree burns may also progress to third-degree burns during the course of several days after injury. Burns over less than 20% TBSA can be treated with oral hydration. Blisters are generally left intact initially if possible. They may later require débridement.

56.5. Which of the following is an indication for intubating a patient who was found in a burning house?
A. Facial edema
B. Fire occurred in a closed space
C. Patient unable to handle own secretions
D. Singed eyebrows
E. Soot in the airway and singed nasal hair

Answer: C. See Box 56.1. Traditionally, inhalation injury was diagnosed on the basis of clinical findings, such as facial burns, singed nasal vibrissae, carbonaceous sputum, and a history of injury within a closed space. However, these findings are neither highly sensitive nor highly specific. Nonetheless, these patients must be closely observed for potential delayed airway compromise.

56.6. What is the most appropriate management for a superficial partial thickness burn on the forearm?
A. A clean dry dressing, such as gauze
B. A commercially available silver containing dressing
C. Systemic antibiotics and silver sulfadiazine
D. Topical antibiotic ointment
E. B and D

Answer: E. Superficial partial thickness burns may be treated with a topical antibiotic ointment or one of several commercially available silver releasing dressings. Silver sulfadiazine, as well as dry dressings, will slow reepithelialization. Silver sulfadiazine is appropriate for infected or heavily contaminated burns. Systemic antibiotics are not indicated for non-infected burns.
CHAPTER 57

Chemical Injuries

Michael D. Levine

PRINCIPLES

During the past century, there has been a dramatic increase in the number of chemicals produced. Worldwide, there are more than 5 million known chemicals, with new chemicals developed annually. Although large incidents, such as the methyl isocyanate release from a pesticide plant in Bhopal India or the release of 4-methylcyclohexanemethanol in the Elk River in West Virginia draw large-scale media attention, many smaller chemical spills occur daily.

It is estimated that 25,000 to 35,000 chemical incidents occur annually in the United States, with the majority resulting from either equipment failure or human error. Approximately 5000 individuals will suffer injuries as a result of these spills. Among those patients injured, nearly half occur among the general public. Individuals living close to an industrial complex may be exposed to a chemical following inadvertent release from the industrial site. However, other individuals living far from any stored chemicals may be exposed due to accidents during transport. It is estimated that half of all pesticide or agricultural chemicals spills occur during transport. The transport of hazardous materials occurs daily throughout the United States. These chemicals, which include acids, alkalis, and other highly reactive substances, not only are found throughout industry but also are ingredients in many household products. Exposure to these substances can result in injuries to many organ systems, including the eyes, skin, and lungs.

A hazardous material (HazMat) is defined as any substance, including gases, solids, or liquids, that has the potential to cause harm to people or the environment. Previously, the Hazardous Substances Emergency Events Surveillance (HSEES) system collected information on chemical exposures. In 2010, the National Toxic Substances Incidents Program (NTSIP) was established. It compiles data from multiple sources to perform chemical surveillance. The most commonly released hazardous substances are volatile organic compounds, herbicides, acids, and ammonia. Various other products, such as cement, drain cleaners, and gasoline, are also potentially quite hazardous, and exposure can result in severe disability or death.

Community Preparedness and HazMat Response

Hazardous materials are found in residential, urban (eg, manufacturing), and rural (eg, agricultural) settings. Furthermore, because these substances are often transported on highways and railroads, a HazMat exposure could potentially occur in virtually any community. First responders, paramedics, and members of the HazMat response team must work together to identify toxic chemicals and assess hazardous environments. Placards, shipping papers, United Nations chemical identification numbers, and markings on shipping containers help identify the offending agent. The Chemical Transportation Emergency Center (CHEMTREC) in Arlington, Virginia, maintains a 24-hour telephone hotline (Box 57.1) to assist in the rapid identification and management of chemical agents. Standardized placards have been developed by the National Fire Protection Association (NFPA).

This placard uses four diamonds to identify specific hazards associated with this project. In addition, regional poison control centers (see Box 57.1) provide specific health information regarding individual chemicals.

Although placards can identify chemicals in the case of an industrial chemical, occasionally it is not known that there is a chemical exposure. These challenges in identification of a HazMat scene are highlighted in Japan, where there has been an epidemic of chemical suicides inside locked cars from hydrogen sulfide gas. Following widespread Internet awareness of this situation, there has become a subsequent increase of similar fatalities in the United States. Such exposures put first responders on particularly high risk of chemical injury, because they may be unaware of any exposure to chemicals by history.

Contingency Plan

The contingency plan for HazMat management is divided into two parts: initiation of the site plan and evacuation. Initiation of the site plan begins after the specific offending agent has been identified and the surrounding environment has been assessed. Only after the substance has been identified can the risks to the public and the environment accurately be identified. First responders should be trained to recognize the potential for a HazMat incident and should establish a perimeter. For the evacuation phase, the HazMat technicians are specifically trained in the use of personal protective equipment (PPE), establishing entry into a HazMat scene, victim rescue, and determining the type and extent of a HazMat emergency. A central command post should be used to coordinate the activities of the HazMat team with those of the emergency medical services personnel, firefighters, police officers, and other relevant personnel.

CLINICAL FEATURES

Most chemical agents cause skin damage by producing a chemical reaction rather than a hyperthermic injury. However, certain chemicals can generate significant heat production via an exothermic reaction after exposure to moisture. Nonetheless, the majority of dermal injuries result from direct damage to the skin rather than from a hyperthermic injury. The type of chemical reaction produced depends on the properties of the individual agent. In general, the degree of damage is directly correlated with the toxic agent’s concentration and duration of exposure. Several other factors also contribute to the degree of injury—for example, areas of the body where the skin is particularly thin are more at risk than areas of the body where the skin is thicker. Skin that is thin or broken is at risk for more severe injury.

DIFFERENTIAL DIAGNOSES

Exposure to acidic compounds can produce protein denaturation and subsequent coagulative necrosis. This eschar limits the depth by which an acid can penetrate. Various acids produce eschars with characteristic colors. For example, nitric acid burns result in a yellow eschar, whereas sulfuric acid burns result in a black or
Important Phone Numbers to Assist in the Identification and Management of Chemicals and Chemical Injuries

CHEMTREC: 1-800-424-9300
Poison Control: 1-800-222-1222

The initial management of the chemically burned patient involves removing the individual from the hostile environment. Because various chemicals will continue to destroy tissue until it is removed from the skin, clothing should be removed, and prompt decontamination measures should be initiated.

Hydrotherapy involves the gentle irrigation of a large volume of water under low pressure for a prolonged time. Such therapy dilutes the toxic agent and washes it out of the skin. High-pressure irrigation should not be used, because it theoretically can drive the chemical deeper into the tissues, as well as produce splattering of the chemical into the eyes of the patient or rescuer.

At present, water is the agent of acidic or alkali substances. The deleterious effects of attempting to neutralize acid and alkali burns were first noted in experimental models in the 1920s. In those studies, animals with acid or alkali burns that underwent initial irrigation with water survived longer than animals treated with chemical neutralizers. It was hypothesized that neutralizing agents produced additional heat, thereby augmenting the burn. Although the same effect may occur when certain chemicals come in contact with water, large volumes of water tend to limit the exothermic reaction. More recently, scientists are beginning to question the belief that neutralization of an alkaline burn of the skin with an acid does increase tissue damage because of the exothermic nature of acid-base reactions. However, these data are preliminary and limited, and therefore we recommend irrigation with water alone as the best method for decontamination.

Not all agents are best decontaminated with irrigation or hydrotherapy. Dry chemical agents, such as lye, should be brushed away before hydrotherapy is instituted. Elemental metals (eg, sodium or potassium) may produce exothermic reactions when combined with water. To minimize the exothermic reaction from such compounds, mineral oil is applied to the skin first. However, copious irrigation should not be delayed while waiting for mineral oil. In addition to lye and elemental metals, some have argued that phenol (carbolic acid) should not be irrigated with water owing to concern for enhanced skin penetration after exposure to water. However, the use of a substance that has both hydrophobic and hydrophilic properties (ie, polyethylene glycol [PEG]) has not been proven to exhibit clear benefit over water alone; therefore if hydrotherapy is to be initiated, hydrotherapy should not be delayed while waiting for PEG. If PEG solution is used for decontamination, the molecular weight of the preferred solution should be 200 to 400 daltons, which is different from the molecular weight of the PEG solution used for colonoscopy preparations and gastric decontamination.

Patients should be treated in a similar manner as with thermal burns. Those meeting referral for burn center criteria should be transferred to a burn center (see Chapter 56). Those with minor symptoms, in whom pain is controlled, and who lack systemic symptoms can be referred home. In contrast, those patients with systemic toxicity, significant opioid analgesic requirements, and those requiring systemic administration of an antidote (eg, intravenous calcium for hydrofluoric acid) should be admitted.

OCULAR INJURIES

Principles

Chemical burns to the eye require emergent management. Alkali burns are more common than acidic burns. Unilateral involvement is more common than bilateral involvement. Common causes include inadvertent handling of chemicals with resultant splash injury, exploding batteries, airbag deployment, and intentional assaults.
Clinical Features

Alkali burns can initially appear trivial, but because of an interaction with lipids in the corneal epithelial cells, a liquefactive necrosis results, and deep penetration through the corneal stroma can ensue. The injury can occur rapidly; for example, anhydrous ammonia can penetrate into the anterior chamber in less than 1 minute, resulting in complete blindness.

There are numerous grading systems that have been developed to describe ocular burns. Historically, the Roper-Hill classification has been used, which divides burns into four grades. However, because anyone with more than 50% limb ischemia is classified because anyone with more than 50% limb ischemia is classified together, this classification has been criticized. Due to changes in surgical treatment and improved outcomes, a different classification scheme has been developed in an attempt to overcome the deficiencies of the Roper-Hill classification (Table 57.1). When comparing the Dua and Roper-Hill classifications in a prospective trial, the Dua classification was found to yield superior prognostic characteristics.

Differential Diagnoses

The differential diagnosis for a red eye or vision loss is broad and is more fully discussed in Chapter 19. In the setting of trauma, the differential diagnosis includes subconjunctival hemorrhage, perforation, foreign body, and corneal abrasions. In the absence of trauma, the differential diagnosis includes benign etiologies (such as, subconjunctival hemorrhage or conjunctivitis) to more concerning etiologies (such as, iritis, uveitis, episcleritis, glaucoma, optic neuropathy, central retinal artery occlusion, or central retinal vein occlusion).

Diagnostic Testing

Visual acuities should be performed in all patients with ocular complaints. The pH of the eye should be checked with litmus paper, ideally before and after irrigation. If the patient can tolerate the procedure, a comprehensive slit-lamp examination is advised.

Management

When a chemical injury to the eye is suspected, copious irrigation is started immediately. At the scene, it is recommended that the victim submerge the eyes in running tap water and continuously open and close the eyes with the head turned such that the affected eye is lower than the unaffected eye to minimize any contamination into the unaffected eye. In the ED, tap water irrigation can be continued during preparation for a more definitive irrigation system. The repeated application of topical anesthetics (such as, proparacaine) can decrease pain and facilitate irrigation. Hydrotherapy can also be accomplished by connecting intravenous tubing to a bag containing normal saline or lactated Ringer’s solution. The initial therapy consists of continual irrigation of the eye with 2 L of normal saline during the first 30 minutes. A Morgan lens can be used for irrigation, although there is a theoretic risk of trapping the chemical between the conjunctiva and the Morgan lens, thereby increasing the burn. If a Morgan lens is used, we recommend replacing the lens between saline applications. After 2 L has been infused, as described earlier, litmus paper is inserted into the conjunctiva to determine the pH; irrigation is continued until the pH is at a near-physiologic level (pH of 7.4). Alkali burns are likely to require more irrigation than acidic burns. For very severe acid or alkali burns, prolonged irrigation may be needed regardless of a normal ocular pH. It is important to also exert the upper eyelid and visually inspect the area for any lodged or hidden particulate matter. A slit-lamp examination with fluorescein staining should be performed to assess for any corneal abrasion. Although of undetermined benefit, ocular antibiotics are recommended after decontamination if a corneal abrasion is present.

The use of topical or subconjunctival corticosteroids following alkali burns has been associated with reduced corneal opacity, vascularization, and inflammation. Ascorbate has been hypothesized to promote new collagen deposition. In addition, there is some data on the use of vitamin C for the treatment of corneal burns.

Disposition

Immediate ophthalmologic consultation and close follow-up are indicated for all significant exposures. All but the mildest burns should be treated with a long-acting cycloplegic and a mydriatic. After consultation with an ophthalmologist, a carbonic anhydrase inhibitor may be used for 2 weeks (or until the pain disappears). These medications decrease the potential for pupillary constriction, increased intraocular pressure, and early glaucoma. Procedures such as amniotic membrane patching, anterior chamber paracentesis, and corneal transplant have been used for chemical injuries to the eye but should be performed by the ophthalmologic consultant.

Patients with lower grade ocular injuries can often be managed as outpatients, but patients with higher-grade injuries should be admitted to the hospital.

Hydrofluoric Acid

Principles

Hydrofluoric acid is an acidic aqueous solution made from the element fluorine. It is used in the petroleum industry to manufacture high-octane gasoline. It is also used in the production of microelectronics and for etching glass, removing rust, and cleaning cement and bricks. It is available in many over-the-counter products in concentrations ranging from 6% to 12% but can be used in the industrial setting in concentrations exceeding 70%. Absorption of hydrofluoric acid can occur after exposure to the lung, skin, and eyes. In a 20-year review of all hydrofluoric acid deaths reported to the Taiwan Poison Control Center, dermal exposure accounted for 84% of all exposures, and the majority...
Patients with pain refractory to local or subcutaneous calcium administration may benefit from regional anesthesia, either in the form of an intravenous infusion (eg, Bier block), or intra-arterially. Various dilute solutions of calcium have been used. One approach is to place an infiltrating mixture of 5% calcium gluconate and 0.9% normal saline subcutaneously. Because the skin is impermeable to calcium, topical treatment is effective only for mild, superficial burns.

Differential Diagnoses

Because pain may seem out of proportion to examination findings, shingles, neuropathy, and other chemical injuries should be considered in the differential diagnosis. In the presence of apparent burns, the differential diagnosis includes blistering disorders, toxic epidermal necrolysis, and infectious etiologies.

Diagnostic Testing

Patients with hydrofluoric acid burns should have serum potassium and ionized calcium levels checked. With electrolyte abnormalities, an electrocardiogram (ECG) should be assessed for dysrhythmias or changes in the QTc or QRS intervals. A chest radiograph should be obtained in individuals with inhalant or pulmonary symptoms. A detailed eye examination, including a slit-lamp examination, fluorescein staining, and visual acuities should be performed on individuals with ocular exposure.

Management

The initial treatment of hydrofluoric acid skin exposure is immediate irrigation with copious amounts of water for at least 15 to 30 minutes. Most exposures to dilute solutions of hydrofluoric acid respond favorably to immediate irrigation. Severe pain or any pain that persists after irrigation denotes a more severe burn that requires detoxification of the fluoride ion. Detoxification is accomplished when an insoluble calcium salt is formed.

Unlike most thermal burns, blisters are removed because necrotic tissue may harbor fluoride ions. The fluoride ions can then be detoxified through topical treatment, local infiltrative therapy, or intra-arterial infusion of calcium. Calcium gluconate (2.5%) gel can be administered to the affected site. Calcium chloride is irritating to the dermis. Calcium gluconate gel is often not available in hospital pharmacies, but it can be made by mixing 3.5 g of calcium gluconate powder in 150 mL of a water-soluble lubricant (eg, glycerin-hydroxyethyl cellulose lubricant [K-Y Jelly]). This gel is secured by an occlusive cover (eg, powder-free latex glove). Because the skin is impermeable to calcium, topical treatment is effective only for mild, superficial burns.

Infiltration Therapy

Subcutaneous. Infiltrative therapy is necessary for treatment of deep, painful hydrofluoric acid burns. Calcium gluconate is the agent of choice and can be administered by either direct infiltration or intra-arterial injection. A common technique involves injecting 0.5 mL/cm² of 10% calcium gluconate subcutaneously through a 27- or 30-gauge needle. The use of an equal volume mixture of 5% calcium gluconate and 0.9% normal saline has been shown to reduce irritation of tissues and decrease subsequent scarring.

Despite its wide acceptance, the infiltration technique has disadvantages, especially in treating digits. A regional nerve block is recommended because the injections may be very painful. Removal of the nail to expose the nail bed is required if subungual tissue is involved. Vascular compromise can occur if excessive fluid is injected into the skin exposure sites, and unbound calcium ions have a direct toxic effect on tissue. Because of these disadvantages with subcutaneous infiltration in the hand, we recommend intra-arterial infusion of in most instances.

Intravenous and Intra-Arterial. Patients with pain refractory to local or subcutaneous calcium administration may benefit from regional anesthesia, either in the form of an intravenous infusion (eg, Bier block), or intra-arterially. Various dilute solutions of calcium have been used. One approach is to place an...
intravenous catheter in the hand or foot involving the affected burn. The extremity is elevated for 1 minute, and a double-cuffed tourniquet is inflated to 40 kPa. An elastic bandage is then placed at 8 kPa. Subsequently, 15 mL of calcium gluconate gel, diluted with 35 mL of 0.9% normal saline, was infused over 2 minutes. The tourniquet is then deflated over 20 minutes. Another approach involves the administration of a mixture of 10 mL of solution of 10% calcium gluconate in 40 to 50 mL of normal saline infused over 4 hours. Because of ease of administration, we recommend starting with this approach, although other approaches can be used in conjunction with this approach if pain persists. If more than 6 hours has elapsed since the time of hydrofluoric acid exposure, tissue necrosis cannot be prevented, even though pain relief can be achieved up to 24 hours after exposure. There is a direct correlation between the speed by which arterial infusion of calcium administration occurred and both the time of wound healing and the need for surgical intervention. The intra-arterial infusion technique has potential disadvantages. Arterial spasm or thrombosis may result in significant skin loss. The intra-arterial procedure is more costly, because it requires hospitalization for the use of the infusion pump and the monitoring of serum calcium concentrations if repeated infusions are used. Recently, the use of epidermal growth factor was found to be superior to saline, calcium gluconate, or magnesium sulfate.

Ocular Exposures

The ocular use of calcium gluconate is somewhat controversial, because it has the potential to cause further damage to the eye. The use of ocular calcium gluconate is not routinely recommended. In the ocular setting, use of Hexafluorine may be considered after copious irrigation of the eye.

Systemic Toxicity

Hydrofluoric acid binds calcium and magnesium ions with strong affinity. Systemic manifestations of fluoride toxicity are related to hypocalcemia and include abdominal pain, muscle fasciculations, nausea, seizures, ventricular dysrhythmias, and cardiovascular collapse. Burns as small as 2.5% of the total body surface area have proven fatal in concentrated hydrofluoric acid exposure. Hypocalcemia can occur after significant exposure to hydrofluoric acid and is corrected with the intravenous administration of a 10% calcium gluconate infusion. Calcium chloride can be used, but its administration requires central access. In addition, fluoride ion accumulation has cardiac and neurotoxic effects.

Disposition

Patients treated with calcium therapy with continued refractory pain should be hospitalized for observation and toxicological consultation. Patients with significant hydrofluoric acid exposure with systemic toxicity require hospitalization to monitor for cardiac dysrhythmias for 24 to 48 hours.

Formic Acid

Principles

Formic acid is a caustic organic acid used in the rubber, paper, tanning, and electroplating industry, along with the manufacturing of disinfectants. It is also used agriculturally.

Clinical Features

Formic acid causes cutaneous injury by inducing a coagulative necrosis. Systemic toxicity occurs after absorption and is manifested by metabolic acidosis, gastrointestinal bleeding, bowel perforation, and aspiration. Because of its ability to induce oxidant stress, hemolysis may occur.

Differential Diagnoses

Similar to hydrofluoric acid, the differential diagnosis includes various other chemical burns, infectious etiologies, toxic epidermal necrolysis, and blistering disorders.

Diagnostic Testing

No specific diagnostic testing is indicated. If the patient shows any signs of systemic toxicity, in addition to a complete blood count and serum electrolytes, the acid-base status should be measured with an arterial or venous blood gas.

Management

Copious wound lavage should be instituted immediately. Acidosis (pH <7.30) should be treated with sodium bicarbonate. Mannitol may be used to expand plasma volume and promote osmotic diuresis in patients with hemolysis. Folinic acid, which enhances formate degradation, can be administered for severe toxicity. Hemodialysis may be required for patients with systemic toxicity, renal failure, and metabolic acidosis. Exchange transfusion may be required for patients refractory to the medical management, including hemodialysis.

Disposition

Patients should be treated according to local burn center referral guidelines. Those who meet criteria for evaluation in a burn center should be referred. Other patients, including those without systemic manifestations and those who are not requiring significant doses of parenteral analgesics, can be discharged home with close-out patient follow-up. Specific treatment recommendations and disposition decisions can be discussed with a regional poison control center (see Box 57.1).

Anhydrous Ammonia

Principles

Anhydrous ammonia is a colorless, pungent gas used extensively as a fertilizer in the agricultural setting. It can also be used in the manufacture of explosives, petroleum, plastics, and synthetic fibers. In addition, the “dry cook” method of methamphetamine production uses anhydrous ammonia as an amphetamine precursor. This method was associated with numerous burns due to anhydrate ammonia. In recent years, due to changes in legislation, the use of anhydrous ammonia has often been substituted with ammonium nitrate or ammonium sulfate based products in a so-called “one pot” method. Nonetheless, its use continues in methamphetamine production. Anhydrous ammonia can be transported as a pressurized liquid. The sudden release of liquid ammonia can cause injury through two distinct mechanisms.

Clinical Features

Anhydrous ammonia is generally stored at an extremely low temperature (−33°C). Consequently, exposure to liquid at this temperature can result in tissue necrosis and frost bite. Second, the ammonia vapors readily dissolve in the moisture in skin, eyes, oropharynx, and lungs to form hydroxyl ions that cause chemical burns by liquefaction necrosis, which can result in full-tissue skin loss. The severity of injury is directly related to the concentration...
Phenol and Derivatives
Principles

Phenols are used industrially as starting materials for many organic polymers and plastics. They are widely used in the agricultural, cosmetic, and medical fields. Because of their antiseptic properties, they are also used in many commercial germicidal solutions. A number of phenol derivatives (e.g., hexylresorcinol and resorcinol) are more bactericidal than phenol.

Phenol (carbolic acid) is an aromatic acidic alcohol with a characteristic odor. The concentration of phenol is inversely related to its depth of burn, because highly concentrated solutions result in coagulation of the keratin, thereby preventing deeper penetration. Histologic studies have demonstrated that 100% concentrations of phenol produce 35% to 50% less penetration than a 50% solution.

Both phenol and its derivatives are highly reactive, corrosive poisons that damage cells by inducing cell wall disruption, protein denaturation, and coagulative necrosis. After penetrating the dermis, phenol produces necrosis of the papillary dermis. This necrotic tissue may temporarily delay its absorption.

Clinical Features

When skin comes in contact with phenol, treatment should be instituted immediately. The exposed area is irrigated with large volumes of water delivered under low pressure. Because dilute phenol solutions are more rapidly absorbed through skin than concentrated solutions, gentle swabbing of the skin surface with sponges soaked in water should be avoided. Any hair, including a beard or mustache, that has come in contact with a phenol is removed as soon as possible, because the phenol can become trapped in hair. Because of its lipophilic nature, it can easily penetrate the dermis, producing not only local findings, but systemic manifestation.

In animal studies, exposure to as little as 0.6 mg of phenol per kilogram can be lethal. Systemic toxicity of phenol primarily affects the central nervous system (CNS) and cardiovascular system. In the CNS, toxicity can manifest as stimulation, lethargy, seizures, or coma. Conduction disturbances can be either tachycardic or bradycardic in nature. Marked hypotension may occur as a result of central vasomotor depression, in addition to a direct toxic effect on the myocardial cells and small blood vessels. Hypothermia and metabolic acidosis can also occur.

Differential Diagnoses

The differential diagnosis includes burns from any other chemical or heat, blistering disorders, dermal infections, hydrofluoric acid exposure, methyl salicylate toxicity, and toxic epidermal necrolysis.

Polyethylene Glycol Therapy

Experimental studies indicate that water alone is effective in reducing the severity of burns and preventing death in animals with skin exposed to phenol and its derivatives. The most effective treatment is undiluted PEG (molecular weight 200 to 400 Daltons) or isopropanol (isopropyl alcohol). Adequate supplies of either PEG or isopropanol should be stocked in hospitals located near areas of phenol use and can often be found in the chemical section of hospital pharmacies. A quick wipe of the skin with PEG solutions reduces mortality and burn severity in experimental animals. These solutions can be used for phenol burns of the face, because they are not irritating to the eyes. Decontamination with water
should be performed until a PEG solution is obtained. Large amounts of water must be used, however, because small amounts are detrimental, enhancing dermal absorption of phenol. Removal of phenol should be undertaken in a well-ventilated room so that hospital personnel are not exposed to high concentrations of phenol fumes.

Treatment of Systemic Toxicity

The treatment of systemic symptoms is primarily supportive. Respiratory depression may require ventilatory support. Hypotension is best treated with an initial fluid bolus of 20 cc/kg of 0.9% normal saline or lactated Ringer’s solution. If fluids administration is inadequate, vasopressors should be used. Metabolic acidosis can be treated with sodium bicarbonate until the pH is near 7.40. The alkalization can also help prevent hemoglobin precipitation in the nephron as a result of hemolysis. Benzodiazepines (lorazepam or diazepam) may be required to treat seizures caused by CNS stimulation. Intravenous lidocaine may be effective in treating ventricular dysrhythmia.

Disposition

Patients without systemic manifestations and not otherwise meeting local criteria for a burn center can be discharged after a period of 6 to 8 hours of cardiac monitoring, providing there are no arrhythmias or other manifestations of systemic toxicity. Those with significant pain requirements should be admitted.

Phosphorus

Principles

Phosphorus is a nonmetallic element that exists in three forms: elemental phosphorus, white phosphorus, and red phosphorus. White phosphorus, which is also referred to as yellow phosphorus, is widely used in munitions manufacturing, in fireworks, as an ingredient in methamphetamine production, and in fertilizers. Historically, it has also been used as a rodenticide. The autoignition temperature (the temperature at which spontaneous combustion can occur) is 30°C (86°F). When white phosphorus comes in contact with air at temperatures above the autoignition point, the phosphorus spontaneously oxidizes, forming phosphorus pentoxide. Phosphorus pentoxide can combine with small amounts of moisture in the air, forming phosphoric acid. In wounds, oxidation of phosphorus pentoxide will continue until it is removed through debridement, neutralized, or consumed.

Clinical Features

Tissue injury from white phosphorus appears to have both thermal and chemical causes. The corrosive action of the phosphoric acid results in an exothermic reaction, thereby liberating heat and causing a thermal burn. The hygroscopic action of the phosphorus pentoxide is also responsible for causing a chemical burn, which frequently results in a partial-thickness or full-thickness burn.

After oral ingestion of white phosphorus, three stages of toxicity are described, although it is uncommon that all three stages occur. The first stage, which can last 8 to 24 hours, is characterized by gastrointestinal tract irritation, including vomiting, abdominal pain, diarrhea, and gastrointestinal bleeding. The stool is occasionally described as being luminescent or “smoking.” Hypovolemic shock can result. Up to one third of patients who ingest significant quantities of white phosphorus will die during this stage. The second stage is a latent phase. During this period, which can last 1 to 3 days, symptoms appear to be improving. However, the third stage is characterized by multisystem organ failure, including hepatic failure, renal failure, and CNS depression. Renal failure is usually present at days 1 to 4, whereas jaundice typically manifests at days 3 to 5.

Red phosphorus can cause some gastrointestinal illness if consumed orally but is less toxic than white phosphorus.

Differential Diagnoses

The differential diagnosis depends on the type of phosphorous exposure. For isolated burns, the differential diagnosis includes thermal or chemical burns (acids or alkalies), infectious etiologies, and blistering disorders. For those with significant gastrointestinal illness, heavy metal toxicity (eg, lead, mercury, thallium, arsenic, and iron), as well as ischemic bowel and causes of gastrointestinal bleeding should be considered.

Diagnostic Testing

Metabolic derangements can also occur after white phosphorus exposure, including hypocalcemia and hyperphosphatemia. Conduction system disturbances, including bradycardia, QT prolongation, and ST and T wave abnormalities, can occur and are partially explained by electrolyte derangements. These ECG changes may explain the sudden early death that may occur in patients with relatively minor white phosphorus burns.

Management

The out-of-hospital management involves the immediate removal of contaminated clothing, followed by submersion of the injured skin in cool water. Warm or hot water is avoided because white phosphorus becomes liquid at 44°C (111°F). Phosphorus particles are removed from the victim’s skin and submerged in water. The burned skin is covered with towels soaked in cool water during transport to the ED.

After the patient arrives at the ED, the burned skin is washed copiously with normal saline. In the past, some advocated use of a suspension of 5% sodium bicarbonate, 3% copper sulfate, and 1% hydroxyethyl cellulose. Other, similar solutions containing copper sulfate have also been described. The use of 0.9% normal saline solution, however, has demonstrated better effects than copper-containing solutions. Although there are some conflicting recommendations in the literature, given that saline is as efficacious as copper sulfate solutions and has less associated toxicity, we recommend saline irrigation as the preferred irrigating solution.

Phosphorus particles can be identified with either ultraviolet light or copper-containing solutions. When a Wood’s lamp is used, the phosphorus will fluoresce under an ultraviolet light. Unlike copper-containing solutions, the use of a Wood’s lamp is not associated with any adverse or detrimental effects. The use of the copper-containing solutions causes the phosphorus particles to become coated with black cupric phosphate. These black particles are more easily identified and thus more easily removed. Copper sulfate also decreases the rate of oxidation of the phosphorus particles, thus limiting their damage to the underlying tissue. However, because the blackened particles can still cause tissue damage, they should be removed. If a copper solution is used, after 30 minutes of exposure to the burned skin the copper-containing solution must be thoroughly washed from the skin, thereby limiting the development of systemic copper toxicity.

After copious irrigation with saline solution decontamination, and treatment of associated electrolyte disturbances, definitive management of the skin burns is accomplished as with any other burn wound. Serum calcium and phosphate levels should be monitored for 24 to 48 hours.
Disposition

Patients with significant phosphorus exposures should be admitted to a monitored setting. Those with burns that would otherwise meet criteria for referral to a burn center should be transferred as per local guidelines.

Methemoglobinemia

Principles

Both nitrates (NO₃⁻) and nitrites (NO₂⁻) are abundant in rural and industrial settings. Both sodium nitrate and sodium nitrite are used in food preservatives. Nitrates also have many medicinal uses secondary to their vasodilatory properties. Nitrates are commonly used in electroplating, engraving, and metal casting and as fertilizing agents. Exposure to either nitrates or nitrites has been associated with methemoglobinemia.

Reduced hemoglobin contains four heme groups, each with a ferrous (Fe²⁺) ion. Methemoglobinemia results when the ferrous ion becomes oxidized to the ferric (Fe³⁺) ion. Methemoglobinemia results when the ferrous ion becomes oxidized to the ferric (Fe³⁺) state. Under routine physiologic conditions, the body reduces the ferric valence back to the ferrous valence via cytochrome b₅ reductase. At any given time, methemoglobin accounts for 1% to 2% of circulating hemoglobin. Cyanosis from methemoglobin occurs when methemoglobin concentrations exceeded 1.5 g/dL.

Clinical Features

Methemoglobin toxicity exists along a spectrum. Many patients with low levels are asymptomatic. When methemoglobin concentrations in nonanemic individuals exceed 20%, headache, anxiety, dyspnea, and tachycardia can occur, although some individuals may be asymptomatic with levels exceeding 30%. Confusion, lethargy, and acidosis typically occur with methemoglobin levels approaching 40% to 50%. Coma, seizures, hypotension, dysrhythmias, and death occur when levels exceed 70%. Patients with anaemia can develop symptoms at lower methemoglobin percentages and in the setting of profound anemia, cyanosis may not be apparent.

Differential Diagnoses

The differential diagnosis includes exposure to any agent that can cause oxidant stress, including local anesthetics, phenazopyridine, dapsone, and arsine gas. In addition, hemolysis from non-oxidant stress should be included on the differential diagnosis.

Diagnostic Testing

The diagnosis of methemoglobinemia should be sought in any cyanotic patient whose pulse oximetry displays a saturation of 85% to 88% that is unresponsive to oxygen therapy and whose arterial blood appears “chocolate brown” in color. The methemoglobin level can be measured on an arterial blood gas analyzed with standard co-oximetry.

Management

Asymptomatic patients are treated by rapidly removing the offending agent. For symptomatic patients without glucose-6-phosphate dehydrogenase (G6PD) deficiency, 1 to 2 mg/kg of a 1% methylene blue solution can be administered over 3 to 5 minutes. A repeat dose may be needed in cases of severe toxicity. Methylene blue acts via the enzyme nicotinamide adenine dinucleotide phosphate (NADPH) methemoglobin reductase, in which NADPH converts methylene blue to leukomethylene blue, which in turn donates an electron to reduce methemoglobin. For those patients who fail to respond to methylene blue, or those with severe G6PD deficiency with concurrent severe toxicity from methemoglobinemia, exchange transfusion may be required.

Disposition

Patients without systemic toxicity and no evidence of methemoglobinemia can be discharged home after 6 hours, as long as the cutaneous burn is not too severe to warrant referral to a burn center as per local guidelines. Patients who develop methemoglobinemia should be observed on a monitored setting for 24 hours, even if the methemoglobinemia resolves after treatment with methylene blue.

Hydrocarbons

Principles

Hydrocarbons are a heterogeneous group of organic compounds that are derived from carbon and hydrogen molecules. They are found in fuels, solvents, paints, paint and spot removers, dry cleaning solutions, lamp oil, rubber cement, and lubricants.

Hydrocarbons are classified as aromatic, in which the carbon moieties are arranged in a ring, or aliphatic, in which the carbon moieties are arranged in a linear or branched chain. Halogenated hydrocarbons are a subgroup of aromatic hydrocarbons in which one of the hydrogen molecules is substituted with a halogen.

Clinical Features

The toxicity from hydrocarbons can affect many different organs, but the lungs are the most commonly affected. The toxicity of hydrocarbons is directly related to their volatility and inversely related to the viscosity and surface tension. The primary toxicity from hydrocarbons occurs from pulmonary aspiration. Thus substances with high volatility, low viscosity, and low surface tension are most likely to be aspirated.

Systemic toxicity from dermal exposure to a hydrocarbon is relatively rare. Significant dermal exposures can occasionally cause local tissue irritation.

Differential Diagnoses

The differential diagnosis includes exposure to any agent that can cause a chemical pneumonitis, as well as infectious pneumonia, acute exacerbation of a reactive airway disease, or pulmonary edema.

Diagnostic Testing

We recommend obtaining a chest radiograph 6 hours after ingestion, although no randomized study has demonstrated this approach to be superior to observing the patient for clinical manifestations of aspiration (eg, coughing gagging vomiting, wheezing, tachypnea, or hypoxia). If the patient is persistently hypoxic on pulse oximetry, an arterial blood gas measurement is recommended.

Management

Treatment involves removal of the patient from the source of exposure and removal of any contaminated clothing. Copious irrigation with warm water should be performed and burns managed as are other thermal injuries.

Chronic dermal exposure can result in perioral or perinausal dermatitis with pyoderma. This so-called “huffer’s rash” is...
part II

Trauma | SECTION THREE

Soft Tissue Injuries

732

primarily seen with recreational abuse. The hydrocarbon inhalant can dry the skin, thereby causing microscopic cracks and allowing bacteria to enter, causing a bacterial superinfection.

Significant toxicity from inhaled (nonaspiration) exposure to hydrocarbons is also unlikely to produce serious effects. Some patients may develop mild headache, dizziness, nausea, or wheezing. These symptoms resolve after removal of the patient from the source of exposure.

Ingestion of hydrocarbons can result in aspiration and systemic toxicity. After ingestion of hydrocarbons, it is recommended that patients be monitored for 6 hours. There is no role for gastric decontamination. Beta-agonists can be administered for bronchospasm, and supplemental oxygen administered as needed. Endotracheal intubation is occasionally required for severe hypoxia and aspiration pneumonitis. Neither corticosteroids nor empirical antibiotic administration are indicated. Antibiotics may be warranted, however, if a superimposed bacterial infection develops, which will typically occur several days after the chemical pneumonitis develops.

Disposition

A patient can be discharged home after a 6-hour observation period, assuming no symptoms develop during the observation period and a chest radiograph (if obtained) is negative. All other patients warrant admission to observe for progression of symptoms and treatment of hydrocarbon-induced pneumonitis.

Tar

Principles

There are two types of hot tar: coal tar pitches and petroleum-derived asphalts. Both products are heated to maintain a liquid form. Roofing tar needs to be heated to temperatures of at least 232°C to achieve desirable viscosities. Deeper burn injuries are associated with burns from roofing asphalt.

Clinical Features

When hot, liquefied tar comes in contact with skin, heat is transferred, and thermal injury results. The tar cools and solidifies on the skin, making removal difficult.

Management

Burns from hot tar present a treatment challenge. When hot tar touches skin, it rapidly cools, solidifies, and becomes enmeshed in the hair. It is important to facilitate this cooling process by adding cold water to the tar at the scene of the accident. Cooling tar with cold water limits the amount of tissue damage and prevents the spread. The tar is continually washed with water until it has cooled and hardened. After cooling, the skin is dried with towels to prevent systemic hypothermia.

Adherent tar should not be removed at the scene of the accident. In the ED, definitive care of the burn injury involves early removal of tar, because it occludes injured skin and encourages bacterial growth. Tar adheres to skin because it is enmeshed in the hair, not because of a direct bond between epidermis and tar.

Solvents used to remove tar ideally should have a close structural affinity to tar. Both petroleum-based aromatic hydrocarbon solvents and surface-active agents, such as polyoxyethylene sorbitan (Tween 80) and petroleum-based (De-Solv-it), have been used to facilitate tar removal. In addition, the use of topical neomycin can enhance removal. Use of these surface-active agents is an effective, safe, and inexpensive means of removing tar from skin. Sunflower oil, NISA baby oil, mayonnaise, and butter have also been used to remove adherent tar from skin, requiring 30 to 90 minutes for complete removal. Sunflower oil has proved effective and safe in removing tar without causing further skin damage.

Asphalts are susceptible to both aromatic (eg, naphthalene) and aliphatic (eg, hexadecane) hydrocarbon solvents, whereas coal tars are susceptible only to aromatic hydrocarbons. Broad-spectrum antibiotic ointments can be used both to help with removal and to help prevent infection. If used, they should be removed and a new coating applied every hour until all the tar has been removed. This process typically takes 12 to 48 hours. Commonly used antibiotic ointments include bacitracin (400 µg/g), polymyxin B (5000 U/kg), and neomycin (5 mg/g). Antibiotic ointment can be used to remove tar layered over the cornea and conjunctiva.

Disposition

Patients with significant burns requiring multiple doses of parenteral analgesics should be admitted. Those who meet criteria for referral to a burn center should be transferred as per local guidelines. Other individuals can be discharged home with close, expedited out-patient follow-up and detailed wound care instructions.

Elemental Metals

The elemental metals, such as lithium, sodium, and potassium, are harmless unless they come in contact with water. When this happens, a violent exothermic reaction occurs that produces heat, hydrogen gas, and hydroxide. Explosions are possible. The evolved heat is sufficient to ignite the hydrogen gas, which results in further heat production and thermal burns. The formation of the hydroxide compound may also result in significant chemical injury to tissue. The reaction occurs more rapidly with elemental potassium than with sodium. These deleterious effects of potassium have been attributed to trace amounts of potassium superoxide released on exposure to room air. Water lavage is therefore contraindicated in these circumstances.

Chromium

Chromium burns can produce systemic toxicity. Death may occur with burn surface areas exceeding 10%. In addition to local wound effects, systemic toxicity can result including hemolysis and renal failure. It has been suggested that early excision may reduce systemic complications, although there is no experimental evidence to support such a practice. Medical management of chromium toxicity remains the mainstay of therapy. Chelation therapy with ethylenediaminetetraacetic acid (EDTA) has not been proven to be of clinical benefit.

Miscellaneous Gases

Chlorine

Chlorine gas was used in World War I as part of chemical warfare. Today, exposure to chlorine most commonly results from accidental industrial exposure. As was demonstrated when a recent chlorine leak from a train car and spread over the city of Festus, Missouri, individuals not directly involved with industry can be exposed.

Chlorine is a heavy greenish-yellow gas or liquid with a characteristic odor. The combination of bleach (sodium hypochlorite) with an acid produces chlorine gas, and the combination of bleach and ammonia produces chloramine gas. Both chlorine and chloramine gas produce similar toxicities. The clinical effects observed after chlorine or chloramine exposure are directly related to the time and concentration of the gas. Mild exposure may simply...
cause mucosal membrane irritation, whereas more severe exposure will induce edema of both the upper airway and the lung parenchyma. Large acute exposure can induce wheezing, cough, and dyspnea. Acute lung injury and/or adult respiratory distress syndrome can result in severe cases. Because these gases are primarily reactive only at a local level, absorbed systemic effects are not commonly observed. Following large exposure, fatalities can occur.20

Phosgene

Similar to chlorine, phosgene was also used in World War I as a weapon, but it remains widely used today in industry.21 Phosgene reacts with water to form carbon dioxide and hydrochloric acid. Given that phosgene is relatively water insoluble, high concentrations are needed before enough hydrochloric acid can be produced to cause mucosal membrane irritation. Phosgene undergoes acetylation to produce lung injury, which can manifest as delayed pulmonary edema. The timing of the pulmonary edema is inversely related to the degree of exposure.

The first step in treating an exposure to chlorine, chloramine, or phosgene gas is removal of the individual from the environment. After significant exposure to these agents, the patient's cardiopulmonary status should be assessed. Endotracheal intubation may be required. Bronchospasm is treated with beta-agonists, such as albuterol. Irritation of the eyes is managed with copious irrigation with water or saline, followed by an assessment for corneal abrasions if persistent eye irritation is noted. Nebulized 4% sodium bicarbonate can be used for treatment of chlorine or chloramine gas exposure. There is limited evidence of the use of nebulized acetylcysteine (1 to 2 g; 5 to 10 mL of a 20% solution) following phosgene exposure.21 The use of corticosteroids has not been proven to be beneficial in the treatment of chlorine, chloramine, or phosgene toxicity. A study of mice exposed to chlorine gas demonstrated improved outcomes following systemic administration of nitrites.22 However, we do not recommend the use of systemic nitrites to treat chlorine exposure.

Nitrogen Oxides

Nitrogen oxides include nitrogen dioxide (NO₂), nitric oxide (NO), and nitrous oxide (N₂O). NO₂ toxicity can occur from the burning of nitrocellulose, from use of Zamboni machines in poorly ventilated areas, and from silo filler’s disease, in which the gas accumulates within a silo of decomposing grain. NO₂ fumes can often be easily recognized because of their reddish-brown color. The nitrogen oxides can cause respiratory tract irritation. Toxicity varies somewhat depending on the oxide, but severe toxicity can result in delayed pulmonary edema, hypotension, hemoptysis, and methemoglobinemia.

Zinc or aluminum phosphide pellets are often used as rodenticides. When the phosphide pellets come in contact with water, phosphine (PH₃) gas is formed. In addition, PH₃ gas can also be formed during the production of methamphetamine from red phosphorus. Inhalation of PH₃ gas produces near instantaneous symptoms. Toxicity occurs via several mechanisms, including free radical formation, inhibition of cytochrome oxidase, and increased lipid peroxidation. Both pulmonary toxicity and gastrointestinal toxicity can result after exposure to PH₃ gas. Common pulmonary symptoms include cough, chest tightness, and dyspnea, followed later by pulmonary edema and acute lung injury. Vomiting, diarrhea, and abdominal pain are also commonly encountered. Coma, hypotension, renal failure, and various dysrhythmias have been described.23,24 Treatment is largely supportive. However, there is limited evidence suggesting beneficial effects of intravenous N-acetylcysteine and magnesium.25-27 Given the potential toxicity of aluminum or zinc phosphide and the relatively minimal harm and cost associated with these therapies, the risk/benefit ratio probably favors treatment with these agents.

Phosgene, phosphene, NO₂, nickel carbonyl, diborane, and zinc smoke bombs can cause delayed-onset pulmonary edema. Therefore, patients exposed to these chemicals are best admitted for 24 hours of observation to the hospital of observation unit, even if asymptomatic early on in the clinical course. In addition, chlorine gas, chloramine gas, cadmium, and polymer fume fever can cause delayed pulmonary edema. However, unlike the former group of gases, with which patients can be asymptomatic for hours and then develop pulmonary edema, delayed pulmonary edema is unlikely with chlorine, chloramine, cadmium, and polymer fume fever in the absence of earlier pulmonary symptoms, and asymptomatic individuals who have been exposed to these chemicals therefore do not require prolonged observation.

Chemical Terrorism

Principles

After the terrorist attack on September 11, 2001, the public has become increasingly aware of chemical terrorism. Despite being banned by the 1925 Geneva Convention, chemical weapons have been used in both the military and the civilian arenas for many years, including the decades preceding the September 11 attack. In the 1980s, chemical weapons were employed against Iraqi civilians. In 1995, Aum Shinrikyo, a Japanese cult, released sarin nerve gas in the Tokyo subway, causing 12 deaths and more than 5000 casualties. In 2013, sarin nerve gas was used by military forces in the Syrian civil war. A more complete discussion of chemical and biological weapons are in Chapter 193.

As terrorist organizations continue to use unconventional weapons such as chemical and biologic agents, the civilian medical community needs to better understand their characteristics and pathophysiology.

Response

The United States government recognizes the emerging threat of terrorism and the potential for terrorist organizations to use non-conventional weapons. Appropriate casualty triage remains a critical component of dealing with unconventional weapons. Triage should be performed by specially trained emergency medical personnel who are familiar with these agents and with the use of PPE. The ED could be quickly overwhelmed with masses of noncritically injured survivors. Ideally, triage would be conducted both at the scene of the attack and again at a second point before ED arrival. The greatest challenge for EDs in caring for these individuals is the sudden increase in patients requiring treatment in addition to the day-to-day surge capacity of the hospital.

Chemical Agents

Chemical agents are classified as (1) nerve agents, (2) vesicants, (3) choking agents, or (4) cyanide and related toxins (Table 57.2). The first nerve agent documented was tabun, which was synthesized by German chemist Gerhard Schrader in 1937. Schrader developed tabun (military symbol: GA) while researching new insecticides. The following year, sarin (GB) was created. The ED could be quickly overwhelmed with masses of noncritically injured survivors. Ideally, triage would be conducted both at the scene of the attack and again at a second point before ED arrival. The greatest challenge for EDs in caring for these individuals is the sudden increase in patients requiring treatment in addition to the day-to-day surge capacity of the hospital.
### Nerve Agents

#### Principles

The nerve agents are classified as either “G” agents or “V” agents. The nerve agents are all derived from phosphoric acid and are volatile liquids at room temperature. As such, they must be aerosolized or evaporated to be used as inhalational weapons. Because the vapors are heavier than air, they tend to remain close to the ground and will travel downwind and downhill.

The nerve agents function by affecting acetylcholine (ACh). ACh receptors are found on the postsynaptic receptor of cholinergic synapses. These receptors can be either nicotinic or muscarinic. Activation of the nicotinic receptors results in depolarization of the postsynaptic neuron or skeletal muscle cell, whereas muscarinic activation affects exocrine glands and smooth muscle, primarily in the CNS. Under normal conditions, the enzyme acetylcholinesterase hydrolyzes ACh in the synapse, thereby inactivating ACh. The primary mechanism of action of the nerve agents is to prevent acetylcholinesterase from hydrolyzing ACh. As a result, excess ACh accumulates in the synapse. The effects at the muscarinic receptors include excess secretions and smooth muscle contractions.

#### Clinical Features

The mnemonics DUMBELS (diarrhea, urination, miosis, bronchocstriction or bronchorrhea, emesis, lacrimation, and salivation) and SLUDGE (salivation, lacrimation, urination, defecation, and gastrointestinal emesis) are often used to describe these effects. The nicotinic manifestations include muscle fasciculations and weakness. The primary lethal clinical effects are respiratory and treatment should be aimed at correcting these effects.

#### Differential Diagnoses

The differential diagnosis of a nerve gas exposure includes gastroenteritis, ischemic bowel, ketoacidosis, pulmonary edema, and reactive airway disease. Other cholinergic agents such as carbamate insecticides and herbicides (eg, paraquat and diquat) are differential diagnosis considerations.

#### Diagnostic Testing

Plasma and red blood cell cholinesterase levels should be obtained, although they may not return in a timely manner in the ED setting. Patients should also have a chest radiograph, ECG, arterial blood gas, and electrolytes obtained.

#### Management

Victims of dermal exposure are undressed and thoroughly contaminated with large-volume, low-pressure irrigation with water. After decontamination, the initial treatment is aimed at maintaining an airway and restoring adequate oxygenation and ventilation. If rapid sequence intubation is desired for airway management, the paralytic succinylcholine should be used with caution because the duration of action will be significantly prolonged as normal degradation will be inhibited by the nerve agent. Atropine is a direct-acting antagonist of the muscarinic receptor. Because atropine does not bind to the nicotinic receptors, all nicotinic effects, including weakness or paralysis, will not be reversed. The initial recommended dose is 2 mg of atropine for adults, although much larger doses will likely be required (2 mg every 5 minutes until desired clinical effect). The endpoint for stopping atropine administration is not improvement in heart rate but, rather, drying of desired clinical effect. The traditional dosage of pralidoxime is 30 mg/kg/hr (650 mg maximum). Standard doses of benzodiazepines (diazepam 5 to 10 mg intravenous push [IVP] or lorazepam 1 to 2 mg IVP) are recommended to prevent and to treat seizure activity.

For pediatric patients, if accurate weight-based dosage cannot be achieved, children younger than 1 year old can receive 0.5 mg

*Chemical or common name (military chemical symbol).
atropine, whereas children older than 1 year can receive the standard adult dose of 2 mg atropine as a starting dose. As with adults, the subsequent doses should double (eg, 0.5 mg followed by 1 mg, followed by 2 mg) until respiratory secretions are dried.

**Disposition**

Patients who do not develop any sign of toxicity after a 6-hour observation period can be discharged home. Those with any signs of cholinergic toxicity, respiratory distress, or seizures should be admitted to an intensive care unit.

**Vesicants**

**Principles**

At temperatures below 14°C, mustard exists in the solid form. Once in the liquid or gaseous form, mustard gas can be recognized by its unique garlic or fishlike odor. Mustard vapor is also much heavier than air and, as a result, tends to remain close to the ground. When stored as an oil-based liquid, it can be readily aerosolized and attached to a bomb device or shell. Because vaporization occurs slowly, the risk of injury is much greater in cool environments and closed spaces. Several minutes of exposure can result in skin and eye injury, and exposure for more than 30 minutes can lead to respiratory injury and death.

Mustard gas can enter the body after inhalational, dermal, or oral exposures. After entering the body, it functions as an alkylating agent. The altered molecules then interact with proteins and nucleic acids, forming covalent bonds. Mustard is the only vesicant that does not cause immediate pain.

**Clinical Features**

Several hours after exposure, manifestations of exposure occur. After exposure to aerosolized mustard gas, cutaneous manifestations appear after a latent period of up to 24 hours. Initial dermal symptoms include burning, itching, and erythema, followed by hyperpigmentation, vesicle formation, and, later, bullae. Electrolyte depletion and secondary bacterial infection can occur if the affected body surface area is large. In addition, inhaled mustard gas can lead to vomiting and diarrhea. Myelosuppression can occur within 3 to 5 days of exposure, resulting in leukopenia and thrombocytopenia. Direct mucosal damage in the respiratory tract can occur, resulting in bronchial damage and hemorrhage. The systemic manifestations can occur with any route of exposure.

**Differential Diagnoses**

The primary differential diagnosis includes blistering diseases and cutaneous infections, such as toxic epidermal necrolysis. Burns from any chemical or thermal agent may present with similar dermatological findings.

**Diagnostic Testing**

A complete blood count should be obtained and reassessed daily for several days to assess for the development of myelosuppression. Those with pulmonary exposure should have a chest radiograph performed. Individuals with gastrointestinal illness should have serum electrolytes measured.

**Management**

Treatment consists first and foremost of removing the patient from the environment and decontaminating the vesicant. If available, water can be used for decontamination but may not be the preferred agent. Currently, the United States military recommends using an alkaline hypochlorite solution (pH 10 or 11) as the decontamination method of choice; a 0.5% hypochlorite solution (diluted household bleach [1:9]) is another alternative. However, these solutions should not be used on open abdominal or chest wounds. No specific antidote exists. British antilewisite (BAL; 2,3-dimercapto-1-propanol; dimercaprol) was originally developed as an antidote for lewisite. Although BAL is currently available as a chelator for other heavy-metal poisonings (eg, mercury, arsenic), we do not recommend its use for mustard gas poisonings.

**Disposition**

Patients with extensive exposure to mustard gas should be admitted to the hospital for monitoring, dermal care, fluid resuscitation, and serial assessment for pancytopenia.

**Cyanide**

**Principles**

Cyanide salts and hydrocyanic acid are commonly used for metal cleaning, precious metal extraction, photographic processes, electroplating, laboratory assays, and jewelry cleaning. In addition, cyanide gas is often liberated from the combustion of plastic-containing compounds. Iatrogenic cyanide toxicity can result from exposure to cyanogens, including plant or herbal cyanogenic glycosides, nitriles, and nitroprusside. There is growing concern that cyanide may be used as a terrorist weapon of mass destruction.

**Pathophysiology**

Cyanide is a cellular toxin. It binds to both Fe³⁺ and cobalt. By binding and inactivating the enzyme cytochrome oxidase, which is part of cytochrome a₃ on the electron transport chain, cyanide inhibits oxidative phosphorylation. This inhibition results in profound cellular hypoxia and death.

**Clinical Features**

After ingestion of cyanide, patients experience sudden cardiovascular collapse coma and profound metabolic acidosis. A characteristic odor of bitter almonds is frequently discussed but only rarely clinically noted.

**Differential Diagnoses**

The primary differential diagnosis is hydrogen sulfide and azide gas exposure. Carbon monoxide should be included on the differential diagnosis, and these two conditions may occur simultaneously particularly in house or industrial fires.

**Diagnostic Testing**

Although cyanide levels are confirmatory, they are rarely immediately available. However, most patients with significant cyanide exposure will have a profound lactic acidosis. In addition, because the cellular utilization of oxygen is blocked, venous blood is highly oxygenated. Therefore, an elevated mixed venous oxygen saturation, or an elevated peripheral venous partial pressure of oxygen (PvO₂) may be observed. Cyanide toxicity commonly results in shortening of the QT interval, with subsequent “T-on-R” phenomena. The pulse oximeter reading may be near normal in cyanide toxicity, despite significant cellular hypoxia.
Hydroxocobalamin (Cyanokit) is the most recently introduced antidote for cyanide intoxication. Hydroxocobalamin binds to cyanide to form cyanocobalamin, which subsequently undergoes renal excretion. Hydroxocobalamin appears to be safe for use in both the hospital and the out-of-hospital settings. Emergency clinicians should be made aware that administration may result in a red discoloration of the skin, which is not a true allergic reaction. Its use is also associated with alteration in laboratory measurements of magnesium, iron, aspartate aminotransferase, total bilirubin, and creatinine. In treating a patient for known or suspected cyanide toxicity (even if in combination with carbon monoxide poisoning), sodium thiosulfate and hydroxocobalamin can be safely administered.

Disposition

Patients with a brief exposure without any manifestations of toxicity can be discharged home after an observation period of 6 hours. One notable exception includes those with exposure to agents that get metabolized to cyanide (eg, acetonitrile); individuals with exposure to these agents should be admitted to an intensive care unit for 24 hours. Any patient with metabolic acidosis, coma, or seizures should be admitted to an intensive care unit.

First responders should wear PPE when rescuing a patient unresponsive after cyanide gas exposure. Patients with cyanide salts on their skin must have the particulate matter brushed off, followed by topical irrigation; decontamination from other routes of exposure is rarely indicated. Currently, two specific types of antidotes can be used to treat known or suspected cyanide intoxication. One method of treatment involves the administration of amyl nitrite, sodium nitrite, and sodium thiosulfate. With this combination of medications, amyl nitrite pearls are broken open, and the patient is allowed to breathe a pearl for 30 seconds of each minute. A new pearl is needed every 3 or 4 minutes. Once intravenous access has been established, 300 mg of sodium nitrite (one 10-mL ampule of a 3% solution for adults and 0.12 to 0.33 mL/kg for children) can be administered. Because sodium nitrite is a potent vasodilator, hypotension can ensue. Therefore the sodium nitrite is administered over a minimum of 5 minutes. After sodium nitrite administration, sodium thiosulfate is administered at a dose of 12.5 g (one 50-mL ampule of a 25% solution for adults and 1.65 mL/kg for children). The function of the nitrites is to induce methemoglobinemia. Thiosulfate enhances transulfuration of hydrogen cyanide to thiocyanate via rhodanese, which is renally excreted. If coexisting carbon monoxide toxicity is suspected, as can occur with smoke inhalation, nitrites should be avoided.

KEY CONCEPTS

- For chemical injury, the degree of skin destruction is determined mainly by the properties of the toxic agent, its concentration, and the duration of its contact.
- Chemical injuries are commonly encountered after exposures to acids and alkalis.
- HazMats are substances that can cause physical injury and can damage the environment if improperly handled.
- In dealing with HazMat incidents, two distinct goals must be achieved: (1) The HazMat must be contained, fire and explosions should eventually be extinguished, and the site must eventually be cleaned, and (2) people exposed to the HazMat must be decontaminated and treated.
- Decontamination consists of removal of contaminated clothing and hydrotherapy (ie, wash the skin) for the majority of exposures. For lithium, potassium, and sodium exposure, hydrotherapy is contraindicated because of the exothermic reaction with contact with water.
- Alkali burns tend to penetrate deeper than acidic burns; as a result, alkali burns tend to be associated with greater morbidity.
- Hydrofluoric acid burns can be associated with significant hypocalcemia.
- Exposure to various toxic gases can occur from routine industrial settings, and knowledge of these agents is necessary for proper treatment by the emergency clinician.
- Unconventional chemical weapons may be categorized into four major classifications: nerve agents, vesicants, choking agents, and cyanide agents.

### CHAPTER 57: QUESTIONS & ANSWERS

**57.1.** A 34-year-old man presents with burning, erythema, and blurred vision after cleaning liquid is splashed in his eye. Which of the following should you do?

A. Be concerned about acidic burn.
B. Be concerned about alkali burn.
C. Postpone irrigation until confirmation of the type of cleaning liquid.
D. Use a miotic agent.
E. Use copious irrigation until a pH of 7.4.

**Answer:** E. When a chemical injury to the eye is suspected, regardless of the offending agent, copious irrigation should be started immediately. Irrigation with water or normal saline should continue until the pH is at a physiologic level (approximate pH of 7.4). All but the mildest burns should be treated with a long-acting cycloplegic, a mydriatic.

**57.2.** A patient presents to the emergency department (ED) complaining of severe burning of both hands since leaving her building this morning. In her history, you find out that the metal doors of her housing complex had just been cleaned of all rust. She has small blisters on her palms and a white appearance to the skin. What is the next step?

A. Consult plastics for an alkali burn.
B. Leave blisters, cover with bacitracin and gauze.
C. Mix calcium gluconate with KY jelly, apply to hands and cover with gloves.
D. Obtain pain control and prescribe oral clindamycin.
E. Treat as a second-degree burn.

**Answer:** C. The rust cleaning and physical findings are descriptive of a hydrofluoric acid burn. It is also commonly used in the production of microelectronics, etching glass, for removing rust, and for cleaning cement and bricks. Calcium gluconate (2.5%) gel is the preferred topical agent. However, this gel is often not available in hospital pharmacies, but it can be made by mixing 3.5 g calcium gluconate powder in 150 mL of a water-soluble lubricant. The gel should be secured by an occlusive cover, such as a latex glove.

### 57.3. In a hydrofluoric burn, what electrolyte abnormality causes systemic manifestations contributing to this chemical’s significant morbidity and mortality?

A. Hypercalcemia
B. Hypermagnesemia
C. Hypocalcemia
D. Hypokalemia
E. Hyponatremia

**Answer:** C. Hydrofluoric acid binds calcium and magnesium ions with strong affinity. Systemic manifestations of fluoride toxicity are at least partly related to hypocalcemia and include abdominal pain, muscle fasciculations, nausea, seizures, ventricular dysrhythmias, and cardiovascular collapse. Of note, hyperkalemia is often a terminal finding in fatal cases.

**57.4.** A 29-year-old man presents by emergency medical services confused and hypoxic. Vitals signs are blood pressure 100/70 mm Hg, heart rate 120 beats/min, respiratory rate 22 breaths per minute, and an oxygen saturation of 83% despite 100% oxygen via non-rebreathing mask. The arterial blood gas is reported as venous. You see the syringe and note that the color is a chocolate brown. Which of the following should be the next step?

A. Determine the methemoglobin level and prepare methylene blue
B. Methylene blue intravenously
C. Sodium thiosulfate intravenously
D. Urine assessment for “vin rose” coloration
E. Wood’s lamp to aid in the diagnosis
Answer: A. The patient is suffering from methemoglobinemia. For those symptomatic patients without glucose-6-phosphate dehydrogenase (G6PD) deficiency, 2 mL/kg of 1% methylene blue can be administered over 3 to 5 minutes. Symptoms typically improve within 20 minutes. Severe cases can be treated with exchange transfusion. Candidates for exchange transfusion include those with G6PD with significant toxicity from methemoglobinemia or those patients who fail to respond to methylene blue.

57.5. A 21-year-old man presents to the emergency department (ED) with chronic shortness of breath and a “huffer’s rash.” The patient has dry, cracked skin with perioral pyoderma. The cause of these symptoms is most likely which of the following?

A. Anhydrous ammonia
B. Cyanide
C. Hydrocarbons
D. Nitrites
E. White phosphorous

Answer: C. The toxicity from hydrocarbons can affect many different organs, but the lungs are the most commonly affected organ. The toxicity is directly related to the volatility and inversely related to the viscosity and surface tension. Chronic dermal exposure to hydrocarbons can result in perioral or perinasal dermatitis with pyoderma. This so-called “huffer’s rash” is primarily seen with recreational abuse.

57.6. Nerve agent poisoning may be rapidly fatal. Beside appropriate decontamination, which of the following should be administered?

A. British anti-Lewisite 2 mg/kg intramuscularly
B. Methylene blue 2 mg/kg intravenously
C. N-acetylcysteine 140 mg/kg orally
D. Pralidoxime 600 mg intramuscularly
E. Pyridostigmine 1 mg intravenously

Answer: D. Nerve agents work by affecting acetylcholine (ACh) levels via inhibition of acetylcholinesterase. ACh receptors are found on the postsynaptic receptor of cholinergic synapses. These receptors can be either nicotinic or muscarinic. The effects at the muscarinic receptors include excess secretions and smooth muscle contractions. The initial recommended treatment is 2 mg of atropine for adults, although larger doses will likely be required. Pralidoxime should also be administered to patients with suspected or known ingestion with significant symptoms. This agent potentially helps prevent irreversible inhibition of the acetylcholinesterase enzyme.

57.7. A 31-year-old man was found in his apartment after an apparent suicide attempt. He smells of bitter almonds. He is obtunded with hypotension, tachypnea, and normal oxygen saturation. After decontamination and resuscitation, what is the next step?

A. Atropine
B. Hydroxocobalamin
C. Methylene blue
D. Naloxone
E. Sodium thiosulfate

Answer: B. This patient likely has cyanide poisoning. One method of treatment involves the administration of amyl nitrite, sodium nitrite, and sodium thiosulfate. The U.S. Food and Drug Administration (FDA) approved hydroxocobalamin (Cyanokit) for treatment of cyanide intoxication. Hydroxocobalamin binds to cyanide to form cyanocobalamin, which subsequently undergoes renal excretion.
CHAPTER 58

Sexual Assault

Judith A. Linden | Ralph J. Riviello

PRINCIPLES

The term sexual violence includes rape and sexual assault. Depending on state statutes, rape is generally defined by three characteristics: (1) penetration of an orifice (mouth, vagina, or anus) however slight; (2) by a penis, body part, or object; and (3) with the threat or use of force or incapacitation. Sexual assault is a broader term and includes unwanted touching or fondling of sexual or genital anatomy or forced involvement in or viewing of pornography. According to the 2010 Centers for Disease Control and Prevention (CDC) National Intimate Partner and Sexual Violence Survey (NISVS), 1 in 5 women and 1 in 71 men have been victims of actual or attempted sexual assault in their lifetimes, with 1.3 million women in the United States reporting having been raped in the previous year. Nationally representative data on nonfatal injury-related emergency department (ED) visits has revealed that 4.2% of all assault-related visits to the ED were for sexual assault. Most of these victims were women. The lifetime prevalence of sexual assault for women presenting to the ED for any reason has been shown to be 39%. Male victims are often younger than 9 years; female victims are most likely to be ages 10 to 19 years. Given the prevalence and role that emergency clinicians play in evaluating victims of sexual assault, emergency clinicians should be comfortable evaluating, treating, and coordinating their care. In many areas, specialized sexual assault teams or forensic examiners are available to assist with care and forensic evidence collection. The care team often includes an emergency nurse, rape crisis advocate, and/or social worker and may involve the local police, sexual assault detective(s), and forensic examiner. The emergency clinician’s responsibilities include responding in a compassionate and nonjudgmental manner, diagnosing and treating acute injuries and administering medications to prevent pregnancy and sexually transmitted infections (STIs), offering forensic evidence and comprehensive toxicology testing when appropriate, and providing linkages to support and follow-up services.

The ED evaluation and treatment of the rape victim can take hours and requires the coordination of multiple resources. Evaluation and treatment of the rape victim has medical, legal, and forensic aspects. Medical stabilization and evaluation should always take priority over forensic evaluation. It is not the emergency clinician’s responsibility to determine if a rape occurred; this is the role of a jury at trial. The role of the emergency clinician is to record objectively information heard, observed, examined, or photographed. In many cases, a trained forensic examiner will be available to complete the forensic evidence collection process. Even years after the event, the emergency clinician may be called to testify in the event of a trial, necessitating thorough and accurate documentation.

CLINICAL FEATURES

Many sexual assaults are never reported to police or health care providers. Victims who report to the police and who sustain injuries are more likely to present to the ED for evaluation. Many victims present with concerns about injuries, risk of pregnancy, or contracting STIs (including human immunodeficiency virus [HIV]). Victims may present with mental health concerns, including depression, anxiety, and suicidal ideation. Acquaintance and intimate partner rape is less commonly reported to police and health care providers. When these victims do present to the ED, they are more likely to present in a delayed manner, when medications to decrease pregnancy rates and STI transmission are less likely to be effective. Most patients who present to the ED with the complaint of sexual assault are women. Although some studies have reported a similar age distribution for males and females, others have noted that males are assaulted at a younger age (<12 years). Populations at increased risk for sexual assault include the homeless, those with severe disabilities (eg, serious injury, chronic disease, chronic mental health problems), incarcerated men and women, and the young. Other populations at increased risk include college-aged women (especially freshman), nonheterosexuals, those who use drugs and alcohol, and sex workers.

Patients who come to the ED with the complaint of sexual assault or rape may present with injuries related to the assault, with general body injuries in up to 67%. It is not uncommon to have minimal or no genital injury from a rape. Genital findings depend on time to presentation, victim’s age, virginal status and parity, and methods used to evaluate for genital injury (see later, “Medical Forensic Examination”). Nonfatal strangulation, associated with rape, carries a risk of immediate and delayed psychological and medical sequelae, including airway obstruction, pulmonary edema, and vascular dissection leading to stroke. Nonfatal strangulation has also been associated with an increased risk of future lethality (eg, in intimate partner rape).

Rape can occur in the context of force or coercion (forcible rape) or in the context of drug or alcohol ingestion (alcohol or drug-facilitated rape [AOD-FR]). About 50% of all rapes are in the context of alcohol or drug ingestion, especially in the adolescent or college-aged population. Alcohol or drugs may have been ingested voluntarily by the victim or administered surreptitiously by the assailant. Comprehensive toxicology testing should be considered in those presenting within the specific jurisdiction’s time limits (usually within 72–96 hours).

Acute reactions to the experience of sexual assault vary and are influenced by prior sexual assaults or trauma, events surrounding the assault, and preexisting mental health conditions. Victims may appear calm and collected, detached, or be agitated, angry,
Depressed, tearful, or anxious. Anger may be directed outwardly toward health care providers, making interactions between the patient and provider challenging. Rape crisis advocates are helpful in supporting the patient and in helping victims understand that their reaction is a normal reaction to a very abnormal and traumatizing event.

The neurochemical changes in the brain that occur in response to trauma can make recall of details surrounding the assault difficult. Recall may be sporadic and disorganized but may become clearer with time and should not be construed as fabrication. Recent research has focused on the concept of tonic immobility, whereby the victim experiences paralysis, increased muscular rigidity, eye closing, and suppressed vocal cord activity in response to an extremely traumatic event. This phenomenon has been well documented in many nonhuman species. Increasing evidence has suggested that humans may respond this way to a life-threatening event when coupled with inescapability. Although tonic immobility may occur in any traumatic event, it is more common in victims of childhood sexual assault. Victims who report tonic immobility often experience increased feelings of guilt and are at increased risk of developing posttraumatic stress disorder (PTSD). These victims are also less likely to respond to pharmacologic therapy.

### Differential Diagnosis

The purpose of the medical forensic sexual assault examination is to document history and physical findings and collect evidentiary material; it is not to determine whether or not a rape occurred. Final diagnosis and discharge instructions should avoid the words “rule out” and “alleged.” Options may include “evaluation following sexual assault,” “sexual assault,” and “reported sexual assault.” According to published studies, approximately 53% to 71% of sexual assault victims sustain nongenital injuries. Fortunately, injuries are usually minor and rarely require emergent medical or surgical intervention. Most injuries are from blunt trauma and include contusion, laceration, incised wound, bruise, hematoma, sprain or strain, fracture, closed head injury, intracerebral injury, and intra-abdominal injury. Treatment of life-threatening injuries should follow advanced trauma life support (ATLS) and trauma protocols and takes precedence over evidence collection.

### Diagnostic Testing

There are no specific diagnostic tests for sexual assault. Traumatic injuries should be evaluated as per standard protocols. There is no test that can determine if a rape occurred; even visualization of sperm on wet mount by emergency clinicians is notoriously inaccurate. Testing for STIs is controversial in adult sexual assault patients. Despite rape shield laws prohibiting the use of a victim’s past sexual behavior in court cases, there remains concern that the presence of a preexisting STI may be used to discredit the victim’s claim. Furthermore, STI prophylaxis is provided to rape victims and will treat any preexisting STIs. Proponents for testing cite public health concerns; identifying preexisting disease allows for notification of contacts.

In children, the presence of an STI can be conclusive proof of a sexual assault, and STI testing is recommended. We recommend testing adults for STIs if the patient complains of STI signs or symptoms or when the patient requests testing. We recommend routinely testing children and young adolescents.

### Sexually Transmitted Infections

Testing for STIs is controversial in adult sexual assault patients. Despite rape shield laws prohibiting the use of a victim’s past sexual behavior in court cases, there remains concern that the presence of a preexisting STI may be used to discredit the victim’s claim. Furthermore, STI prophylaxis is provided to rape victims and will treat any preexisting STIs. Proponents for testing cite public health concerns; identifying preexisting disease allows for notification of contacts. In children, the presence of an STI can be conclusive proof of a sexual assault, and STI testing is recommended. We recommend testing adults for STIs if the patient complains of STI signs or symptoms or when the patient requests testing. We recommend routinely testing children and young adolescents.

### Alcohol- or Drug-Facilitated Rape

Comprehensive toxicology testing, often performed in specialized forensic laboratories, is recommended in cases of suspected AOD-FR and can test for over 150 illicit and over-the-counter substances. The most commonly detected substances include ethanol, cannabinoids, cocaine, amphetamines, and benzodiazepines. Box 58.1 lists symptoms and conditions suspicious for AOD-FR. Because many substances have a short half-life, toxicologic testing should be performed expeditiously; most protocols obtain specimens up to 72 to 96 hours postassault or after ingestion. Many jurisdictions have specific collection requirements and kits that are sent to comprehensive crime laboratories. At least 100 mL of urine and 12 mL of blood (sodium fluoride tube) should be collected and specimens refrigerated, with chain of custody carefully maintained (Fig. 58.1).

### Box 58.1

**Indications for Comprehensive Toxicology Screening**

- Period of unconsciousness
- Period of loss of motor control
- Amnesia or confused state with suspicion of sexual assault
- Patient suspicion or belief that she or he was drugged prior to or during sexual assault
- Less than 72–96 hours since assault (depending on jurisdictional protocol)

### Fig. 58.1

Example of a forensic toxicology test kit for urine and serum specimens.
partner violence survivors, nonfatal strangulation has a sevenfold increased risk of future attempted and completed homicide. Hypoxia is the final common pathway in strangulation and can occur by three main mechanisms—jugular vein occlusion, carotid artery occlusion, or laryngeal occlusion. Symptoms of dysphagia and odynophagia may accompany physical findings, including facial, neck, and periorbital petechiae (Fig. 58.2) and subconjunctival hemorrhages, the result of venous occlusion causing increased intravessel pressure and rupture. Other possible findings include bruising on the neck in the shape of fingerprints (Fig. 58.3) and defensive scratch marks on the neck from the victim attempting to pry off the assailant’s fingers (Fig. 58.4). Alteration in consciousness, neurologic complaints, and urinary and fecal incontinence may result from restricted blood flow to the brain. Direct laryngeal injury may lead to vocal cord injury and laryngeal or hyoid fractures. Carotid artery injury, dissection, or intraluminal thrombosis may cause stroke symptoms, which may not present until months or years after the assault.

Imaging should be considered for patients with facial petechiae, loss of consciousness, incontinence, stroke symptoms, or voice changes. Imaging modalities and strategies for patient evaluation are listed in Tables 58.1 and 58.2. We recommend a number of diagnostics tests, including a chest x-ray to evaluate for early pulmonary edema and aspiration pneumonitis, flexible laryngoscopy to evaluate the glottic and supraglottic airways, and computed tomography angiography (CTA) or magnetic resonance imaging should be considered for patients with facial petechiae, loss of consciousness, incontinence, stroke symptoms, or voice changes. Imaging modalities and strategies for patient evaluation are listed in Tables 58.1 and 58.2. We recommend a number of diagnostics tests, including a chest x-ray to evaluate for early pulmonary edema and aspiration pneumonitis, flexible laryngoscopy to evaluate the glottic and supraglottic airways, and computed tomography angiography (CTA) or magnetic resonance imaging.

Fig. 58.2. Petechiae in nonfatal strangulation. A, Eyelid petechiae following the nonfatal strangulation of a child. B, Neck petechiae seen in the same patient in A. There is also an abrasion present on the left side of the neck and ecchymosis of the left and right mandibles. (Courtesy Training Institute on Strangulation Prevention, San Diego, CA; used with permission.)

Fig. 58.3. Neck bruising in nonfatal strangulation. A, Circular neck bruising following manual strangulation. This injury is referred to as a fingertip bruise. B, Other bruises of the neck in the same patient, most likely made by the assailant’s fingers.

Fig. 58.4. Claw marks in nonfatal strangulation. The patient caused these injuries as she attempted to pry the assailant’s hands off of her neck. (Courtesy Training Institute on Strangulation Prevention, San Diego, CA; used with permission.)

*Imaging modality chosen will vary based on institution-specific protocols and availability of imaging modalities.*

Imaging (MRI) to evaluate for arterial dissection (most commonly, carotid). 35,36 Patients with persistent unconsciousness, laryngeal fracture, carotid injury, or neurologic symptoms should be admitted to the intensive care unit for close monitoring. Patients with reported loss of consciousness, incontinence, facial or conjunctival petechiae, or signs and symptoms of soft tissue neck injury, or who are under the influence of drugs or alcohol, should be admitted to the hospital or observed for 12 to 24 hours and monitored for delayed symptoms of injury. Patients with no loss of consciousness, minimal to no physical findings, no intoxication, and a safe discharge environment can be discharged home with instructions to watch for late development of complications.

**MANAGEMENT**

Management of the sexually assaulted patient requires an organized victim-centered and trauma-informed approach, defined by institutional protocols and available support resources. In most cases, a sexual assault forensic examiner (SAFE) or sexual assault nurse examiner (SANE) will perform the evidentiary examination. Hospitals should have a protocol concerning the activation of the SAFE team. If there is no SAFE team available at the hospital, the American College of Emergency Physicians supports the triage of medically stable sexual assault victims to designated examination facilities for evidence collection by specially educated and clinically trained personnel. 38

On arrival to the ED, the sexual assault patient should be rapidly triaged and placed in a private area or examination room. Other sexual assault response team (SART) members should be mobilized—SANE, social worker, and rape crisis medical advocate. Depending on department protocol, the patient may or may not be evaluated by the emergency clinician. If the emergency clinician sees the patient, it is important to keep the history brief. The goal of the history is to rule out potentially serious injury, determine which medications are needed for prophylaxis, and decide if the patient is in the time limit for evidence collection. Some questions include the following:

- When did it happen?
- What types of assault occurred?
- Where did penetration occur?
- Were any objects used during the assault?
- Have there been symptoms since the assault?
- Was there loss of memory, incoordination, or suspicion for drug-facilitated sexual assault?

As with any ED patient, providers should elicit the patient’s medical problems, medications, past medical history, and last menstrual period.
Medical Forensic Examination

The medical forensic examination should proceed in an organized and coordinated fashion, and the patient should be informed of all steps of the process. The examination can be conducted up to 7 days following assault, depending on jurisdiction policy, with most using 5 days as a cutoff. In cases of oral and anal assault, evidence is usually not collected more than 24 hours after the assault. In vaginal assaults, DNA and sperm can be recovered from the cervix up to 120 hours later. Evidence is collected using a jurisdictionally specific sexual assault evidence kit or physical evidence recovery kit (rape kit). This kit contains all the supplies necessary to collect and properly store recovered evidence (Fig. 58.5).

The patient should consent to the examination and collection of evidence and for evidence (and photographs) to be turned over to law enforcement (Fig. 58.6). The patient has the right to decline any or all parts of the examination and can revoke or change that consent at any time during the process. This is his or her decision and right; this should be reinforced to the victim who may have a sense of powerlessness after a sexual assault. The consent process begins with the forensic examiner explaining the purpose of the examination, steps, and process involved. The forensic examination process should proceed only after the patient has a thorough understanding of the examination process and has consented. The Violence Against Women Act (VAWA) of 1994 created and supports comprehensive, cost-effective responses to sexual, domestic, and dating violence. This act provides financial support for state, tribal, and territory service provision, as well as a grants program. Any state that receives VAWA funding is required to provide a rape examination while not requiring the patient to report to the police. In addition, the VAWA program ensures that patients are not required to leave the victim the option to report to the police at a later date.

In vaginal assaults, DNA and sperm can be recovered from the cervix up to 120 hours later. Evidence is collected using a jurisdictionally specific sexual assault evidence kit or physical evidence recovery kit (rape kit). This kit contains all the supplies necessary to collect and properly store recovered evidence (Fig. 58.5).

The patient should consent to the examination and collection of evidence and for evidence (and photographs) to be turned over to law enforcement (Fig. 58.6). The patient has the right to decline any or all parts of the examination and can revoke or change that consent at any time during the process. This is his or her decision and right; this should be reinforced to the victim who may have a sense of powerlessness after a sexual assault. The consent process begins with the forensic examiner explaining the purpose of the examination, steps, and process involved. The forensic examination process should proceed only after the patient has a thorough understanding of the examination process and has consented. The Violence Against Women Act (VAWA) of 1994 created and supports comprehensive, cost-effective responses to sexual, domestic, and dating violence. This act provides financial support for state, tribal, and territory service provision, as well as a grants program. The Violence Against Women Act (VAWA) of 1994 created and supports comprehensive, cost-effective responses to sexual, domestic, and dating violence. This act provides financial support for state, tribal, and territory service provision, as well as a grants program. Any state that receives VAWA funding is required to provide a rape examination while not requiring the patient to report to the police.
Clothing that has been ripped or torn or shows other signs of force should be collected, taking care not to cut through existing holes or tears. Areas of clothing with possible DNA (including undergarments not worn at the time of assault, but put on later) should also be collected. Clothing and other evidence should be placed in paper bags because plastic promotes mold and bacteria growth and can destroy DNA evidence. If a piece of evidence is wet when collected, the package should be labeled as such, and the police or crime laboratory be made aware of this so that they can dry and repackage the evidence. A minimum of two swabs should be taken when swabbing an area, allowing the crime laboratory to save one swab for future analysis by the defense’s laboratory. In general, wet stains should be collected with a dry swab or cotton tipped applicator; dry stains are collected with a swab moistened with sterile or distilled water. For dried specimens and bite marks, a double-swab technique is performed. First, the area is swabbed in a rolling fashion with a moistened swab, and then a dry one is rolled over the area. All swabs should be allowed to dry by air, using a

Injury Severity Scale (GISS) is another available instrument that uses gross visualization, colposcopy, and toluidine blue staining. Variables include five types of injuries—swelling, color change, tissue break, hymen and introitus injury, toluidine blue dye uptake—and two classes of severity—tissue integrity intact and disrupted. The GISS can help distinguish sexual assault patients from consensual intercourse subjects based on type and class of injury. In a cohort of sexual assault victims, 40% had class B or tissue-disrupted injuries versus 10% in the consensual group. Although not commonly used in clinical practice by emergency clinicians, the GISS has been validated in defining and measuring external genital injury after sexual intercourse and is most commonly used by sexual assault experts.

General Principles of Evidence Collection

Gloves should be worn during collection, processing, and packaging of evidence and should be changed in between each step of evidence collection to avoid cross-contamination of evidence. Text continued on p. 748

DISTRIBUTION OF CalEMA 2-923

Parent

________ (Initial)

I understand that data without patient identity may be collected from this report for health and forensic purposes
and provided to health authorities and other qualified persons with a valid educational or scientific interest for
demographic and/or epidemiological studies.

Patient

________ (Initial)

________ (Initial)

________ (Initial)

I hereby consent to a forensic medical examination for evidence of sexual assault.

I understand that collection of evidence may include photographing injuries and that these photographs may
include the genital area.

I understand that a forensic medical examination for evidence of sexual assault at public expense can, with my
consent, be conducted by a health care professional to discover and preserve evidence of the assault. If
conducted, the report of the examination and any evidence obtained will be released to law enforcement authorities.
I understand that the examination may include the collection of reference specimens at the time of the examination
or at a later date. I understand that I may withdraw consent at any time for any portion of the examination.

Minors: Family Code Section 6927 permits minors (12 to 17 years of age) to consent to medical examination, treatment, and evidence
collection for sexual assault without parental consent. See instructions for parental notification requirements for minors.

Patient Identification

I understand that hospitals and health care professionals are required by Penal Code Sections 11160-11161 to
report to law enforcement authorities cases in which medical care is sought when injuries have been inflicted
upon any person in violation of any state penal law. The report must state the name of the injured person,
current whereabouts, and the type and extent of injuries.

G. ACTS DESCRIBED BY PATIENT

* Any penetration of the genital or anal opening, however slight, constitutes the act.
* Oral copulation requires only contact
* If more than one assailant, identify by number.

1. Penetration of vagina by:
   - No  Yes  Attempted  Unsure
   - Penis
   - Finger
   - Object
   If yes, describe the object:

2. Penetration of anus by:
   - No  Yes  Attempted  Unsure
   - Penis
   - Finger
   - Object
   If yes, describe the object:

3. Oral copulation of genitals:
   - No  Yes  Attempted  Unsure
   - Of patient by assailant
   - Of assailant by patient

4. Oral copulation of anus:
   - No  Yes  Attempted  Unsure
   - Of patient by assailant
   - Of assailant by patient

5. Non-genital act(s):
   - No  Yes  Attempted  Unsure
   - Licking
   - Kissing
   - Suction Injury
   - Sting

6. Other act(s):
   - No  Yes  Attempted  Unsure

7. Did ejaculation occur?  No  Yes  Unsure
   If yes, note location(s):
   - Mouth
   - Vagina
   - Anus/Rectum
   - Body surface
   - On clothing
   - On bedding
   - Other

8. Contraceptive or lubricant products:
   - No  Yes  Unsure
   - Foam used?
   - Jelly used?
   - Lubricant used?
   - Condom used?

H. GENERAL PHYSICAL EXAMINATION

Record all findings using diagrams, legend, and a consecutive numbering system.

1. Blood Pressure
2. Pulse
3. Temperature
4. Exam Started
5. Exam Completed

5. Describe general physical appearance

6. Collect outer and underclothing if indicated:
   - Findings
   - Not indicated

7. Collect dried and moist secretions, stains, and foreign materials from the body. Scan the entire body with a Wood's Lamp.
   - Findings
   - No Findings

8. Collect fingernail scrapings or cuttings according to local policy.

I. HEAD, NECK, AND ORAL EXAMINATION

Record all findings using diagrams, legend, and a consecutive numbering system.

1. Examine the face, head, hair, scalp, and neck for injury and foreign materials.
   - Findings: No Findings

2. Collect dried and moist secretions, stains, and foreign materials from the face, head, hair, scalp, and neck.
   - Findings: No Findings

3. Examine the oral cavity for injury and foreign materials (if indicated by assault history). Collect foreign materials.
   - Findings: No Findings

4. Collect 2 swabs from the oral cavity up to 12 hours post assault and prepare one dry mount slide from one of the swabs.
   - Findings: No Findings

5. Collect head hair reference samples according to local policy.

J. GENITAL EXAMINATION - FEMALES

Record all findings using diagrams, legend, and a consecutive numbering system.

1. Examine the inner thighs, external genitalia, and perineal area. Check the box(es) if there are assault related findings:
   - Findings: No Findings

2. Collect dried and moist secretions, stains, and foreign materials. Scan the area with a Wood's Lamp.
   - Findings: No Findings

3. Collect pubic hair reference samples according to local policy.

4. Examine the vagina and cervix. Check the box(es) if there are assault related findings.
   - Findings: No Findings

5. Collect 4 swabs from the vaginal pool. Prepare one wet mount slide and one dry mount slide.

6. Collect 2 cervical swabs (if over 48 hours post assault).

7. Examine the buttocks, anus, and rectum (if indicated by history).
   - Findings: No Findings

8. Collect dried and moist secretions, stains, and foreign materials.

9. Collect 2 anal and/or rectal swabs and prepare one dry mount slide.

10. Conduct an anoscopic exam if rectal injury is suspected or if there is any sign of rectal bleeding.

11. Exam position used:
   - Supine  Other

12. Exam position used:

TABLE 58.3
Steps in Sexual Assault Evidence Collection Kit—cont’d

<table>
<thead>
<tr>
<th>STEP</th>
<th>TECHNIQUE</th>
</tr>
</thead>
</table>
| Head hair pulling (painful, abandoned by most protocols) | To obtain patient reference DNA  
  • Pull head hair strands from different parts of the scalp to try to obtain the root.  
  • Package, label, and seal. |
| External genital examination and swabs | Obtain biologic evidence from the external GU sites—vulva and perineum—while inspecting for injury.  
  • Use retraction and separation technique to look for evidence of genital injury.  
  • Use moistened swabs to swab the areas.  
  • If matted pubic is hair present, use scissors to cut the matted section.  
  • Package, label, and seal. |
| Internal genital swabs | Obtain biologic evidence from internal GU sites—vagina and cervix—to assess for genital injury.  
  • Use swabs to collect fluid and evidence from the posterior fornices.  
  • Collect any foreign object, such as a tampon or condom.  
  • Insert swab into cervix and gently twirl.  
  • Obtaining STI cultures is done at this time.  
  • Package, label, and seal. |
| Anal examination and swabs | Obtain biological evidence from the anus/rectum and to assess for injury  
  • Gently retract the anus with slow steady pressure to allow natural dilation, and inspect for injury.  
  • Gently insert swabs and twirl.  
  • An anoscope can be used to assess for injury.  
  • Package, label, and seal. |
| DNA reference sample | Obtain a DNA reference sample.  
  • As per protocol, collect a blood or buccal swab sample. |
| General principles | Two sterile cotton-tipped swabs are used simultaneously to collect samples. One will be used for the crime laboratory, and one is available for the defense, if requested.  
  • Dry swabs are used to collect evidence from moist areas; swabs moistened with control sterile water are used to collect evidence from dry areas.  
  • Swabs are air-dried, placed back in the sleeves, and then placed in an envelope.  
  • All evidence is placed in paper (not plastic) because moisture may cause mold growth and destroy DNA. |

GU, Genitourinary; STI, sexually transmitted infection.

Fig. 58.8. Female genitalia. A, Anatomy of the female external genitalia with the clock positions used in documentation. B, Actual photograph highlighting the relative anatomy of the female external genitalia important in a medical forensic examination. (From Roberts JR, Custalow CB, Thompsen TW: Roberts and Hedges’ clinical procedures in emergency medicine, ed 6, Philadelphia, 2013, Elsevier Saunders.)

desiccant pack, or in a swab dryer. The evidence is packaged into envelopes once the examination is completed, and all swabs have dried. The completed evidentiary collection kit is labeled and sealed and, while maintaining chain of custody, stored according to departmental policy or turned over to law enforcement.

The chain of custody describes the path that the evidence takes once it is collected from the body and ensures that the evidence was not tampered with or mishandled. Failure to maintain the chain of custody calls into question validity of the evidence and may make it inadmissible in court. Chain of custody documentation should describe how the evidence was handled and include a log of those who have had contact with it. The medical forensic examination form or rape kit will typically contain chain of custody forms (Fig. 58.13).
Special Techniques

Colposcopy. This is a diagnostic procedure to illuminate, magnify, and photograph or digitally record external and internal genital structures. Having widespread application in gynecology, the colposcope microscopically improves gross visualization. The colposcope has a 4× to 30× magnification and can be equipped with a still or video camera. Colposcopy is superior to gross visualization for detecting anogenital injuries. Most SAFE pro-

grams routinely use colposcopy in their evaluations. Limitations of colposcopy include the cost and size of the instrument, as well as the technical training required for its use. Because of this, several programs use digital photography alone to detect and document genital injury. Although no study has directly compared

Fig. 58.9. Examination of the external genitalia. This illustrates foreign debris (presumed semen and piece of paper) on the external genitalia of a rape victim.

Fig. 58.10. External genitalia injury. Shown are marked swelling and ecchymosis of the right labia major, inguinal area, and buttocks in a middle-aged woman following sexual assault by a single perpetrator.

Fig. 58.11. External genitalia injury. A, Tear and abrasion at the 6 o’clock position of the fossa navicularis. B, Closed arrow is abrasion to the posterior fourchette at 6:30. Open arrow is abrasion of the perineum (anterior to the rectum). Arrowheads are abrasion and ecchymosis of right medial thigh. C, The patient in this picture sustained multiple tears and abrasions. There is a large linear tear extending from the fossa navicularis through the posterior fourchette and onto the perineum all in the midline. There are also tears bilaterally on the labia minora, three at the 7 o’clock position and two at the 5 o’clock position.
**PART II**

**Anal Source.** Light Source. In sexual assault examinations, the ALS is used to scan the body and genitilia uses ultraviolet light to fluoresce biologic material. In sexual assault due to neurologic or cognitive disease, physical

---

**Fig. 58.12.** Anal injury. There is a linear anal abrasion and tear at the 6 o’clock position with the patient in the lithotomy position.

---

colposcopy to digital photography for detecting injury, we recommend colposcopy when available.

**Toluidine Blue Dye.** Toluidine blue dye (TBD) is a stain that adheres to nuclei in damaged epithelial cells and has not been shown to interfere with DNA testing. Zink and colleagues have demonstrated that more tears were identified with TBD enhancement by direct visualization and colposcopy. The dye should be applied prior to speculum insertion because the speculum may introduce genital injury. The dye is applied to the external genitalia and then gently wiped with surgical lubricant, 1% acetic acid solution, or baby wipes to remove excess solution (Figs. 58.14 and 58.15), which can lead to false-positive findings.

**Alternate Light Source.** An alternate light source (ALS) uses ultraviolet light to fluoresce biologic material. In sexual assault examinations, the ALS is used to scan the body and genitilia for areas of fluorescence that can be swabbed and submitted for potential DNA identification. Men and saliva fluoresce under an ultraviolet (UV) light wavelength of 450 nm (range, 390–500 nm). Although the ALS is sensitive for semen, it is not specific. False-positive ALS results may be seen with hand cream, powder, body gel, laundry detergent, fabric softeners, soaps, and other ointments and creams. However, physician training can improve the ability to distinguish semen from other substances (e.g., hand cream, soap, bacitracin). A Wood’s lamp, which emits UV light at wavelengths less than 390 nm, is a poor substitute for an ALS device and is thus not recommended for routine use in detecting biologic evidence.

---

**SPECIAL POPULATIONS**

**Older Adult Sexual Assault**

From 2005 to 2010, the National Crime Victimization Survey reported 0.2/1000 cases of rape or sexual assault occurred in women aged 65 years and older. Older persons may be at risk for sexual assault due to neurologic or cognitive disease, physical disabilities, frailty, and institutionalized living arrangements. In one study, older victims reported verbal threats more frequently. Postmenopausal women are thought to be at particular risk for genital injury due to atrophy of connective tissue, loss of tissue elasticity, and atrophy of vaginal epithelium.

Studies have shown mixed results regarding the severity of genital injury. A recent study of 122 postmenopausal women found that 37% suffered a genital injury compared to 17% of premenopausal women; although postmenopausal women had similar rates of extragenital injury, they were more likely to have sustained large bruises. The locations of the genital injuries are similar to those of younger victims, but older victims tend to have more anogenital lacerations and abrasions. The medical forensic examination of the older victim should proceed in the same manner as for other victims. The history may be difficult due to neurologic or cognitive impairment in the victim. Patient positioning may be more challenging due to physical disabilities; the typical dorsal lithotomy position may not be possible, and other positions (left lateral Sim’s, lateral recumbent, and dorsal recumbent) may be needed for victim comfort (Fig. 58.16). Prophylaxis against STIs and HIV infection should be offered while considering potential medication interactions. Older victims can also suffer major psychological trauma, including PTSD and rape trauma syndrome and should be referred to rape crisis center services.

**Male Sexual Assault**

Male sexual assaults occur in straight, homosexual, and bisexual individuals, college students, prisoners, military personnel, gang members, and institutionalized individuals. According to the 2010 NISVS, 40% of gay men, 47% of bisexual men, and 21% of heterosexual men in the United States have experienced sexual violence other than rape at some point in their lives. Males are raped by men or women, tend to underreport their rape, and seek medical services much less frequently than females. Compared to women, males tend to be of a similar age (20–30 years), report more forcible penetration (52% anal, 15% oral, and 33% both), have more anal trauma and injury, suffer more object and digital penetration, have multiple assailants, have more weapons used, and know their assailant(s) less often. Male sexual assault includes forced oral copulation or vaginal and anal penetration of the victim or assailant. Male victims may ejaculate during the assault due to fear and physical stimulation. This can cause increased feelings of guilt and shame and can often be used to argue in a court of law that the victim was a willing participant.

The forensic history and physical examination proceed in a similar fashion to that for a female victim. During the physical examination, attention is paid to the oral cavity, penis and scrotum, and anus and rectum. See Fig. 58.17 for a diagram of the terminology for male genitalia. Swabs should be taken from the oral cavity, external genitals, and anus. When swabbing the genitals, attention should be paid to all parts of the penis, including the base of the penis and anterior scrotum. The anal and rectal examination should include visualization to look for potential foreign bodies and gross injury, such as tears, abrasions, bleeding, erythema, hematoma, fissures, engorgement, and friability. Anal swabs should be inserted approximately 2 cm into the rectum. Visualization can be enhanced using TBD and anoscopy. Anoscopy has been shown to detect more injuries than colposcopy or an unassisted examination. Significant pain and an inability to tolerate anoscopy may warrant an examination under anesthesia, with some victims requiring surgical evaluation and treatment.

Male victims should be offered similar STI prophylaxis. HIV prophylaxis should be considered given the high risk of transmission from anal receptive and anal insertive intercourse. Victims should also be referred for rape crisis counseling services.

FURTHER CONSIDERATIONS

Definitive Treatment to Prevent Sexually Transmitted Infections and Pregnancy

One of the most common concerns of survivors who present to the ED is that of becoming pregnant and acquiring STIs, including HIV. The risk of becoming pregnant after rape has been estimated at 5% but depends on the age of the patient, use of birth control by the patient and condoms in the assailant, and timing in the menstrual cycle. The risk of acquiring STIs after a rape depends on the local prevalence of the infections. Prior research has shown the risk is greatest for acquiring bacterial vaginosis (19%), trichomonas (12%), Neisseria gonorrhea (4%), and chlamydia (2%). The risk of acquiring HIV is very low, estimated to be 0.1% to 0.3% for receptive vaginal intercourse and 0.5% to 3.0% for receptive anal intercourse (Table 58.4). However, estimates do not take into account the increased risks associated with sexual violence and injuries. The risk of HIV transmission is also related to viral load in the assailant (highest in very early and very late HIV disease), route of assault, and presence of STIs in the victim.

According to CDC recommendations, all sexual assault victims presenting to the ED should be offered medications to prevent pregnancy (women of childbearing potential), STIs, hepatitis B, and HIV (Table 58.5). Many states mandate that emergency clinicians offer pregnancy prevention to sexual assault victims (www.ncsl.org/research/health/emergency-contraception-state-laws.aspx). See Table 58.6 for emergency contraception options. All victims should also be given a tetanus booster, if indicated. HIV postexposure prophylaxis (PEP) should be offered to sexual

aThere are no absolute contraindications to ED, except for an established pregnancy, because they will not be effective.

bLevonorgestrel is not an abortifacient and is not teratogenic.

cUlipristal acetate is not an abortifacient. It has not been tested adequately in human studies in pregnancy or breast-feeding; animal studies showed increased pregnancy loss.

Consultation Center offers online information and telephone consultation for providers who do not have access to a local HIV expert (nccc.ucsf.edu/clinician-consultation/pep-post-exposure-prophylaxis/).

**Disposition**

Most sexual assault patients will be discharged from the ED. There are myriad websites that can assist the emergency clinician who is caring for the sexual assault patient (Box 58.3). If available in the ED, social services and a rape crisis advocate can help formulate a safe discharge plan. Victims of attempted strangulation, especially those with loss of consciousness, bowel or bladder incontinence, or persistent shortness of breath or voice changes, should be admitted for observation. If safe house resources are unavailable, consider admitting patients who do not have a safe place to go. The discharge instructions should include the number of the forensic kit when the examination is performed. Patients should be encouraged to follow up with their local rape crisis center, primary care provider (or other medical provider), and mental health provider, as needed. Medical follow-up should include any needed completion of the hepatitis B series, repeat pregnancy testing, STI testing (if they did not get treated), and repeat HIV testing (at 6 weeks). If they received HIV prophylaxis, they should follow up with the local HIV expert or clinic to have follow-up laboratory testing, monitoring for side effects, and compliance with medications.

Patients may experience subsequent symptoms of PTSD or rape trauma syndrome (RTS). Symptoms may include depression, anxiety, flashbacks, and difficulty sleeping and interacting with friends and loved ones. Acute pain after sexual assault is common and often undertreated, sometimes involving areas that were not traumatized. Delayed or worsening pain in many regions of the body has been shown to occur in up to 60% of sexual assault survivors at 6 weeks and 3 months postassault.

**Testifying in Court**

Although good medical care is the primary goal of ED treatment, the emergency clinician may at times be responsible for collecting sexual assault evidence. In this case, the emergency clinician may be called on to testify in court. The key to competent testimony is preparation and knowledge of the court process.

In most cases, the emergency clinician will be called on as a fact witness or as someone who testifies to what the patient said or did, as well as findings on physical examination. Occasionally, the emergency clinician may be called on as an expert witness. An expert witness has specific training and may be called on to provide an explanation or educate the jury, even if he or she did not actually care for the patient. Box 58.4 outlines the steps in court testimony and includes some helpful suggestions for the emergency clinician in preparation for such a trial.

Although testifying is anxiety-provoking, being prepared, appearing professional, remaining calm, and taking the opportunity to educate the judge and jury will help the emergency clinician feel more confident in his or her testimony.

**KEY CONCEPTS**

- Sexual assault is more common in women, but can happen in gay and heterosexual men, and in lesbian, gay, bisexual, transgender, and gender-nonconforming individuals.
- Sexual assault often results in no physical signs of injury.
- Optimal care includes creating a safe confidential environment while incorporating the principles of trauma-informed care. The patient should be included in decision making and ultimately decide treatment. Options include injury evaluation, treatment to prevent pregnancy and STIs, support and trauma counseling, evidence collection, and comprehensive toxicology testing if within jurisdictional time limits.
- The sexual assault evidence collection examination is an intensive, protocol-driven, multistep process, best performed by a certified sexual assault examiner.
- Adult sexual assault patients should be treated empirically according to CDC guidelines to prevent STIs (including gonorrhea, syphilis, chlamydia, trichomonas, HIV, and hepatitis B), where appropriate. Children and adolescents should be tested and, if symptoms develop, treated for STIs.
- All adolescent and adult female sexual assault patients should be offered pregnancy prophylaxis.
- HIV postexposure prophylaxis should be offered if the assailant is known to be HIV-positive or if multiple assailants are involved or, if the HIV status of the assailant is unknown, offered on a case by case basis.
- Alcohol and drugs may have been ingested voluntarily or involuntarily by the patient. If the patient consents, comprehensive toxicology testing may be appropriate.
- A strangulation attempt with loss of consciousness, bowel and bladder incontinence, persistent voice changes, difficulty swallowing, or shortness of breath should be comprehensively evaluated in the ED. Evaluation options include a chest x-ray, flexible laryngoscopy, and CTA or MRI of the neck. Admission should be considered for persistent symptoms.
- Many victims will not have obvious physical injuries; this does not imply consent or refute a sexual assault.
- The emergency clinician should not determine if a sexual assault happened but should record observations, statements, and findings objectively that were gathered during the course of ED treatment.

**Steps in Court Testimony**

**PREPARATION FOR TRIAL**

1. Respond to the subpoena in a timely fashion; a delay can result in criminal charges for you.
2. Notify and consult with the institutional legal counsel.
3. Update your CV and be able to recite dates of education and certification.
4. Ask to meet with the prosecutor to review the medical records, evidence collection kit, and a list of questions the prosecutor plans to ask the emergency clinician.

**DAY OF THE TRIAL**

1. The day of the trial may change due to motions and order of witnesses.
2. Arrive early and dress in professional attire—a suit is preferred, rather than a white coat.
3. Before testifying, the emergency clinician will be sworn in and seated in the witness box. There are three parts to the testimony—questioning by the prosecution (testimony), cross-examination by the defense attorney, and redirect by the prosecution.

4. In general, the emergency clinician should look at the prosecution or defense attorney when being questioned and the jury when answering questions; this is the provider’s opportunity to educate the judge and jury.
5. Responses to questions should be brief and answer only the question; do not add information and explanations unless asked, and resist using medical jargon such as ecchymosis in favor of clearly understood terms such as bruising.
6. All answers should be verbal, taking care not to nod in response. The line of questioning will often start with asking the provider to state her or his name and then describe training and certification, including how long he or she has been practicing emergency medicine.
7. Do not refer to the patient as the “victim.”
8. If an answer cannot be recalled, then just simply state, “I cannot recall.”
9. Documents can be reviewed in court (eg, medical or evidentiary kit records) on request.
10. If the question is not understood, the emergency clinician can ask the attorney to repeat the question or clarify it prior to answering.
Give hepatitis B vaccination if the patient is unimmunized or uncertain. Follow-up doses should be given at 1 to 2 months and 4 to 6 months (total of three doses). This strategy, which avoids the need for serologic testing, has been shown to be effective. HBIG is not recommended by the CDC after sexual assault (although it is recommended in body fluid exposures in unimmunized health care workers).

58.2. Which of the following empirical antibiotic regimen is indicated for sexual assault patients to prevent sexually transmitted infections?

A. Cefixime, 400 mg PO
B. Cefixime, 400 mg PO once, plus doxycycline, 100 mg PO bid for 10 days
C. Ceftriaxone, 1 g IM (intramuscularly)
D. Ceftriaxone, 1 g IM, plus azithromycin, 2 g orally (PO)
E. Ceftriaxone, 250 mg IM, plus metronidazole, 2 g PO, plus azithromycin, 1 g PO
58.3. Which of the following statements best describes sexual assault in males?
A. Ejaculation should not occur in the victim during male sexual assault.
B. Males are more likely to overreport sexual assault.
C. Males are more likely to require sexually transmitted infection (STI) prophylaxis.
D. Males do not require referral to rape crisis centers.
E. Males may require anoscopy to detect anogenital injuries.

Answer: E. Males may actually suffer more anogenital injuries than women; injury detection can be aided or enhanced by using an anoscope. Males underreport the crime, do not seek medical attention, and absolutely need referral to rape crisis centers for post-rape care and counseling. Males are not more likely to require STI prophylaxis because the risk of transmission per act does not change based on gender. Ejaculation may occur during sexual assault due to prostatic stimulation and fear arousal. This should not be taken to infer that the assault was consensual.

58.4. Sexual assault often leads to injury. Which of the following statements best describes the rate of sexual assault injury in females?
A. Genital injury can be seen following consensual and nonconsensual intercourse.
B. Nongenital injury is uncommon and rarely seen.
C. Resistance of the victim and force used do not influence the risk of genital injury.
D. The precise location of genital injury can be used to confirm sexual assault.
E. The presence of genital injury confirms that a sexual assault occurred.

Answer: A. Genital injury can be seen following consensual and nonconsensual intercourse; its presence or location of injury does not confirm that a rape occurred. Nonconsensual intercourse (sexual assault) is more likely to result in more injuries that can be more severe. Other bodily injury can be commonly seen and may be more common than genital injury. Injury can be influenced by age, virginal status, resistance, force, number of assailants, and relationship of the assailant to the victim.

58.5. Which of the following factors reduces the likelihood of finding genital injury during the sexual assault examination?
A. Digital penetration
B. Increased time since sexual assault occurred
C. Penile penetration
D. Use of foreign object during the assault
E. Victim sexual immaturity

Answer: B. The genital structures heal quickly, so the longer the time since the sexual assault occurred, the less likelihood of finding evidence of injury on examination. All the other factors increase the likelihood of finding genital injury at the time of the sexual assault examination.

58.6. A 25-year-old woman presents 4 days after vaginal penetration. Her body mass index (BMI) is 35. Which of the following is true about emergency contraception (EC)?
A. A pregnancy test is mandatory prior to offering EC.
B. She should be offered levonorgestrel because it is more effective in this situation.
C. She should be offered ulipristal because it is more effective in this situation.
D. She should have an intrauterine device (IUD) inserted because this is the most effective form of EC for her.
E. She should not receive EC because it will likely be less effective due to her BMI.

Answer: C. Emergency contraception should be offered up to 5 days after vaginal assault. Ulipristal, levonorgestrel, and high-dose birth control pills are options. Ulipristal is more effective after 72 hours and in women with a BMI greater than 26. At a BMI above 35, both forms of oral EC are less effective, but should still be administered if there is no alternative. IUD placement is the most effective form of EC; it can be placed up to 5 days after assault. IUD placement allows for ongoing birth control in situations where there is likely to be loss of reproductive control (intimate partner assault), but is often less desirable after assault. IUD placement is most often not available in a timely manner. A pregnancy test is not mandatory prior to giving EC because it will not harm an existing pregnancy. A pregnancy test is suggested prior to ulipristal administration, given the lack of large studies in pregnant women.

58.7. A 28-year-old woman presents following sexual assault, during which the assailant strangled her, and she passed out. Which of the following is true concerning this patient’s injury?
A. Nonfatal strangulation has little impact on the risk of future injury in the domestic violence victim.
B. Regardless of her symptoms, no additional imaging is needed.
C. The hyoid bone is commonly fractured during an attempted strangulation.
D. The signs and symptoms of nonfatal strangulation are usually caused by arterial or venous blood flow occlusion or blockage of air entry through the trachea.
E. There must be physical evidence of injury for it to be a proven case of nonfatal strangulation.

Answer: D. Strangulation leads to hypoxia by jugular vein occlusion, carotid artery occlusion, or blockage of the airway. The hyoid bone is rarely injured. A large percentage of patients may have no physical findings and may require imaging, depending on the signs and symptoms present. In intimate partner violence (IPV) relationships, nonfatal strangulation increases the risk of future homicide sevenfold.
CHAPTER 59

Intimate Partner Violence and Abuse

Esther K. Choo | Judith A. Linden

PRINCIPLES

Background and Importance

Intimate partner violence (IPV)\(^1\) has been defined by the Centers for Disease Control and Prevention (CDC) as the threat or infliction of physical, psychological, or sexual harm by a current or former intimate partner or spouse.\(^1\) Physical violence includes aggressive behaviors, such as pushing, hitting, slapping, punching, kicking, biting, burning, strangulation, and using objects and weapons with the potential to cause death, disability, injury, or other harm. Psychological or emotional violence includes words and behaviors meant to intimidate, degrade, humiliate, or isolate the victim from family and friends, threats, controlling access to clothing, transportation, money, and other basic needs, and limiting professional and social activities. Sexual violence includes using physical force to attempt sexual acts or sexual contact against the victim’s will, or on a victim not able to consent, whether or not the sexual act is completed. Although not explicitly included in the CDC definition, sexual abuse may also include prevention of or interference with the use of birth control (so-called reproductive coercion)\(^7\) and refusal to use condoms to prevent the transmission of sexually transmitted infections (STIs) and human immunodeficiency virus (HIV).\(^7\) Threats of physical or sexual harm are also considered IPV.

According to the CDC’s 2010 National Intimate Partner and Sexual Violence Survey (NISVS), 35.6% of women will experience IPV over their lifetimes, only considering physical violence, rape, and stalking. One in three victimized women experiences multiple forms of IPV.\(^4\) Obtaining accurate national estimates of IPV prevalence among emergency department (ED) patients or even of ED visits directly related to IPV injuries is hampered by poor documentation and coding practices. In the National Hospital Ambulatory Medical Care Survey (NHAMCS), IPV is a recorded diagnosis in less than 0.25% of visits. However, in individual ED studies, observed IPV prevalence in women is disproportionately high compared to the general population, with estimates of recent (6–12 month) prevalence ranging from 12% to 19% (≈8–12 times that of the general population) and of lifetime prevalence from 44% to 54% (≈1.4–1.7 times that of the general population).

IPV commonly occurs against men as well as women. In the CDC’s 2010 NISVS, one in four men reported lifetime physical abuse, stalking, or rape by an intimate partner, and 35% of them reported associated physical or psychological sequelae of abuse.\(^4\) Data from the Behavioral Risk Factor Surveillance System, another nationally representative CDC survey, have reinforced that men experience all forms of IPV and its mental and physical health sequelae.\(^5\) The high prevalence of abuse among men may be partly understood by the fact that IPV is frequently bidirectional. IPV researchers have described two distinct forms of IPV, intimate terrorism and situational couple violence.\(^7\) The two forms are differentiated based on the use of power to control. Intimate terrorism is defined as “the attempt to dominate one’s partner and to exert general control over the relationship,” whereas situational couple violence is “violence that is not connected to a general pattern of control.” Situational couple violence is usually less injurious or severe and more likely to be engaged in by either member of the couple. Intimate terrorism is characterized as more injurious, more frequent, and more often perpetrated by men against women. Overall, women continue to be the primary targets of violence and to experience high rates of health sequelae. Therefore, health care responses to IPV, as well as community resources for survivors, are largely directed toward women.

IPV affects other aspects of health and is associated with risky health behaviors, such as cigarette smoking, heavy alcohol and drug use, and physical inactivity, as well as mental illness (eg, depression, anxiety, posttraumatic stress disorder [PTSD], suicidality).\(^8\) IPV is associated with increased rates of cervical cancer.\(^12\) IPV patients often have poor maintenance of chronic medical conditions such as asthma, diabetes, and chronic pain syndromes.\(^5\) Pregnant IPV victims tend to seek prenatal care late and are at risk for termination of pregnancy, placental abruption, preterm delivery, and low infant birth weight.\(^13\) IPV is responsible for most intentional injuries experienced by women, accounting for 38% of all female homicides globally.\(^17-19\) IPV fatalities do not usually occur as a freak event in an otherwise happy family; IPV is a precursor to the homicide in 65% to 75% of cases.\(^9\) Many IPV homicide victims see a health care provider within the year before their death. ED visits represent an opportunity to identify IPV and those at high risk for future severe injury or death.

The annual economic cost in the United States has been estimated at more than $4.8 billion dollars for direct medical and mental health services and an additional $1.8 billion in lost earnings and productivity,\(^20\) above and beyond those without IPV. Encouragingly, health care use has been observed to return to normal rates several years after the cessation of IPV,\(^9\) suggesting that interventions against IPV may have a positive overall effect on health.

Causes and Natural History of Intimate Partner Violence

IPV is a complex multifactorial phenomenon, influenced by multiple, interconnected societal, community, relationship, and individual factors (Fig. 59.1). Individual-level risk factors include childhood exposure to IPV, presence of a physical or mental disability, and use of alcohol or drugs.\(^22-27\) Relationship factors that may influence IPV occurrence include the couple’s communication and conflict resolution skills\(^28\) and socioeconomic stressors; IPV appears to occur at increased rates in relationships among those with lower income, job or housing instability, and male unemployment. Housing instability also increases the risk of sequelae, such as PTSD, depression, and increased ED use in IPV victims.\(^29\) Lack of social support for women and delinquent peer associations for men have been associated with victimization and perpetration, respectively, whereas bolstering social supports can decrease violence.\(^30\)

Finally, the individual, family, and community all function within an overarching society or culture with its laws, attitudes,
norms, and biases, including overall societal tolerance toward violence. The predominant cultural theory regarding the cause of IPV is so-called feminist theory, which states that violence against women results from gender inequity, both ideologic (belief, norms, values) and structural (access to and positions within social institutions).

In some ways, IPV fits a chronic disease model because it tends be a lifelong condition that recurs in cyclic patterns within a relationship. Additionally, children who have experienced family violence tend to enter future violent relationships. Care for IPV requires systematic screening and multidisciplinary care, with the need for long-term physical and mental health care, counseling and advocacy, legal aid, and long-term strategies for financial and social independence. Approaching IPV as a chronic disease underscores the importance of population-wide screening efforts. In addition to providing acute medical care, emergency clinicians should connect patients who screen positive with primary care physicians and/or domestic violence community agencies to ensure continuity of care for what is typically a long-term, recurring problem.

This chronic disease model is in contrast to traditional clinical thinking about IPV, which is focused around a crisis event, such as injury. A significant body of older literature was dedicated to patterns of injury that might be considered classic signs of IPV. However, physical findings have demonstrated poor sensitivity and specificity for IPV and thus are not amenable to clinical decision rules. IPV can present with any number of symptoms, usually without any injury at all. For this reason, the US Preventive Services Taskforce (USPSTF) has recommended routine screening for IPV in women of childbearing age, even in the absence of overt injuries.

Despite USPSTF recommendations and Joint Commission requirements for robust health system responses to IPV, there are a number of barriers to its identification and management. Emergency clinicians generally receive little training and thus have low confidence in their ability to respond effectively to revelations of abuse. In busy clinical settings such as the ED, the high volume of patients and acuity of disease may preclude screening and more in-depth discussions of partner abuse. Given the complex psychosocial issues that may accompany IPV, emergency clinicians may also fear opening a Pandora’s box, uncovering a range of needs. Staff may be uncertain about whose responsibility it is to screen for IPV, discuss positive screens with the patient, and provide necessary counseling and referrals. Overall, current screening and intervention practices fail to identify women who are at risk for future IPV. Incorporating screening into triage processes, including into electronic medical record documentation, routine training of clinical staff, and use of newer modalities, such as self-administered, computer-based screening, may aid EDs and emergency clinicians in improving the detection of IPV.

**CLINICAL FEATURES**

Classic injury patterns (eg, maxillofacial injuries, multiple injuries, extremity fractures) have demonstrated limited predictive value in screening for IPV. Most IPV victims present to the ED with noninjury visits, including gynecology-related complaints, mental health and substance abuse complaints, pain syndromes, and uncontrolled medical illnesses. Elements of the history that may suggest IPV include a delay in seeking medical care, noncompliance with medications, and/or missed medical appointments; all these may reflect the fact that an abuser is controlling the patient’s...
access to care. Unless probed about the presence of IPV, these patients may not be identified. If the injury is a result of IPV, the patient may be reluctant to divulge the information. Additional historical clues that an injury may be a result of IPV are a vague or changing history, a history that is inconsistent with the injuries, a statement by the patient that he or she is accident-prone, and a past history of injuries.

IPV is often considered in women who present with injuries or assault, but should also be considered in male victims of assault. Although men do report being victims of IPV, reported injuries are commonly abrasions, and the mechanism is often scratching, punching, or being hit with a blunt object.

**Injury Presentations**

Emergency clinicians should ask patients presenting with injuries if they were intentionally inflicted and specifically if injuries were caused by IPV. If the patient attributes the injuries to IPV, the identity of the other person, as well as that person’s relationship to the patient, should be ascertained and documented. Not only is noting the nature of the relationship important for ensuring the accuracy of diagnostic coding, but a victim who is living with an assailant requires different resources compared to a victim of a stranger assault.

IPV patients may come to the ED with acute injuries, or injuries may be an incidental finding discovered during the physical examination for medical complaints. The emergency clinician should look for clues that an injury may be intentional in nature—a central location (eg, trunk, breasts), bilateral injuries (both arms or both legs), defensive injuries (eg, ecchymoses on the back of the hand from protecting the face), and patterned injuries (having the markings of an object such as the sole of a shoe or a burn with the imprint of an iron). Common locations for IPV injuries are the head, face, mouth, and neck. Types of injuries may include facial contusions, lacerations, fractures, traumatic alopecia, concussion, skull fractures, intracranial hemorrhages, and strangulation. Extremity injuries with grab marks (fingertip contusions) to the upper arms are suggestive of IPV.

Emergency clinicians should document injury location, size, swelling, tenderness, coloration, evidence of healing, and presence of a pattern. Certain traumatic injuries are more commonly associated with IPV, such as injuries to the face, head, neck, thorax, and abdomen. Some studies have considered differentiating IPV versus non–IPV-related assaults presenting to the ED. Assaults that occur in the home are more likely to be IPV-related in men and women, and assaults involving a head injury were more likely to be IPV-related in women. While inquiring about who assaulted the patient is important, discovering where the assault occurred can give clues for IPV. Patients given an e-code of IPV are likely to have traumatic diagnoses such as contusion and facial fractures and are also more likely to present with complications of pregnancy.

**Gynecologic-Related Presentations**

IPV victims commonly present to the ED with obstetric and gynecologic complaints. Presentations related to IPV may include unintended pregnancy, requests for emergency contraception and termination of pregnancy, and frequent sexually transmitted infections.38-40 IPV survivors report increased rates of STIs and other gynecologic disorders, such as cervicitis and vulvovaginitis.41-42 Unintended pregnancy and STIs may be a consequence of loss of reproductive control and/or sexual assault. Sexual violence is a common tactic used for intimidation and control in IPV; 46% to 68% of abused women admit to sexual assault in the context of abuse.

The sequelae of intimate partner sexual abuse are at least as serious as those of stranger sexual assault. Victims of intimate partner sexual abuse are more likely to sustain more serious nongenital injuries than victims of stranger assault. Many validated IPV screening tools (Table 59.1) omit questions about sexual abuse or reproductive coercion. Women who are sexually assaulted by an intimate partner or family member are more likely to present in a delayed manner or not present to the ED at all for evaluation. Emergency clinicians should ask all sexual assault victims about IPV and safety at home. IPV patients may not consider themselves raped or sexually assaulted if the perpetrator was their partner, husband, or boyfriend. Thus, emergency clinicians should ask whether the patient has been forced to perform sexual activities rather than having been “raped.”

**Mental Health Presentations**

IPV victims frequently experience depression, suicidal ideation, homicidal ideation, PTSD, insomnia, eating disorders, and alcohol and drug misuse.49-11,41,44 Mental health presentations including substance abuse, therefore, should prompt suspicion for possible IPV. IPV survivors are also more likely to report depression, anxiety, and PTSD and use mental health resources.

Alcohol and Drug Use and Intimate Partner Violence

Whether in the perpetrator or recipient of abuse, alcohol and drug misuse place women at greater risk for physical and sexual intimate partner victimization. Alcohol and drug use may be a coping response to the emotional and physical sequelae of IPV, but can also lead to abuse. Explanations for this include conflicts over substance use—women who misuse alcohol or drugs may be more likely to choose partners who use alcohol and drugs—or that alcohol or drugs impede the victim’s ability to recognize escalating aggressive behavior, navigate tensions, and resolve conflict within a relationship. Overall, alcohol and drug misuse increase women’s vulnerability to IPV victimization and reduces the likelihood that they will be screened for these problems. Those with coexisting problems not only face mental and physical health problems of greater complexity, but must contend with additional challenges to recovery; for example, few substance use treatment programs address violence, and few domestic violence agencies are equipped to address active substance misuse.

Chronic Medical Conditions

IPV patients may seek care for chronic conditions that are a result of previous injuries or are comorbid medical conditions of the abuse. These include psychosocial disorders (substance abuse, depression, anxiety, tobacco use), musculoskeletal disorders (degenerative joint disease, low back pain, joint trauma, cervical depression, acute sprains), reproductive complaints (menstrual disorders, vulvovaginitis, sexually transmitted infections), and others (confusion, headaches, urinary tract infections, abdominal pain, chest pain, respiratory infections, reflux disease, and lacerations).

Other common medical presentations of IPV patients include cardiorespiratory illnesses (palpitations, chest pain, asthma exacerbations, shortness of breath), gastrointestinal disorders (functional bowel disease), and general constitutional complaints (weakness, fatigue, dizziness, chronic pain).

Pain Syndromes

IPV should be in the differential diagnosis as a co-occurring condition and possible contributing factor in patients who present with chronic pain. Chronic pain, including headache, abdominal pain, back pain, and joint pain are common in IPV survivors, and disability and pain symptoms may persist for years after being separated from the abuser. Those with a history of more severe abuse, sexual abuse, and childhood abuse report more symptoms. Asking about and identifying past abuse may decrease unnecessary testing and inappropriate medication administration and facilitate referral to critical resources.

DIAGNOSTIC CONSIDERATIONS

Differential Diagnosis

Human Trafficking

A victim of human trafficking (HT) can be mistaken for a victim of IPV. HT is a form of modern slavery and can present in a similar manner as IPV. HT, however, entails very different dynamics, challenges, and approaches to intervention and resources. The World Health Organization has defined human trafficking as “the recruitment, transportation, transfer, harboring or receipt of persons, by means of the threat or use of force or other forms of coercion, of abduction, of fraud, of deception, of the abuse of power or of a position of vulnerability, or of the giving or receiving of payments or benefits to achieve the consent of a person having control over another person, for the purpose of exploitation.” Exploitation includes, at a minimum, “the exploitation of the prostitution of others or other forms of sexual exploitation, forced labor or services, slavery or practices similar to slavery, servitude, or the removal of organs.” Trafficking of victims can occur across or within national borders. HT victims can be of any age or gender, but are usually women and children, who are often from a poverty situation and are previous victims of sexual or physical abuse. Victims are lured by promises of money, love, or opportunities for success. HT victims are often held in bondage and required to pay large amounts of money in return for transportation, favors, or food and shelter. They are paid little or nothing, and thus are unable to pay back this debt. Trafficking victims often have no autonomy, and access to health care or reproductive control and may be forced to sleep behind locked doors or not allowed to leave their place of employment. They may present to the ED with STIs, pregnancy, injuries, and medical and mental health conditions. HT victims often experience the initiation and forced use of drugs or alcohol, as well as physical, emotional, and sexual violence. They are often controlled with addiction to alcohol or drugs and may present as victims of an overdose in alcohol and drug withdrawal. Trafficking victims can also present with medical complaints, such as headaches, stomach pain, memory problems, back pain, loss of appetite, and tooth pain. Many victims report fatigue, headaches, back pain, weight loss, mental health symptoms such as depression and anxiety, and sexual and reproductive health problems. The severity of symptoms appears to increase with the duration of trafficking. To date, there has been very little research on the health effects and presentations of HT, and most studies have concentrated on young female HT victims. Clues in a patient’s presentation that may suggest trafficking rather than IPV are included in Box 59.1.

Although the emergency clinician may suspect HT, most victims will not be identified in the ED. There are many reasons why a victim of HT might not disclose in the ED which are similar to IPV—shame, embarrassment and self-blame, lack of trust or familiarity with the provider, isolation with lack of economic and

BOX 59.1

Presentations Prompting Consideration of Human Trafficking

- Delay in seeking medical care
- Stated age older than visual appearance
- Evidence of lack of care for previously identified or obviously existing medical conditions
- Discrepancy between stated history and clinical presentation or observed pattern of injury
- Scripted, memorized, or mechanically recited history
- A patient who is overly concerned with the time, contacting their “partner,” leaving the ED
- Subordinate, hypervigilant, or fearful demeanor
- Reluctance or inability to speak on one’s own behalf
- Companion who refuses to leave
- Lack of identification documents, or documents in possession of another party
- Accompanied by individual who answers questions for patient and attempts to control encounter, including insisting on providing interpretation (may be “grandmotherly” type)
- Has tattoos or other marks or insignias that may indicate a claim of “ownership” by another, unwilling or uncomfortable talking about the tattoo
- Evidence of any type of physical violence, including torture
- Frequent relocations
Questions to Identify Human Trafficking

- Do you get paid for the work you do?
- Are you able to leave when you want to?
- Are there locks on the outside of your doors and windows?
- Can you come and go as you want?
- Have you been threatened if you leave your job?

Diagnostic Testing

Diagnostic testing for specific injuries and illnesses related to IPV follows general medical, trauma, and injury guidelines.

Screening

IPV survivors use the ED at high rates. One study of law enforcement–involved survivors has found that 64% had used the ED in the year prior to police identification, and 82% used the ED in the 2 years surrounding law enforcement involvement. Many of these were not identified on review of the ED records, and most of the ED visits (71%) were non–injury-related. Directed screening for IPV involves questioning patients who present with illnesses and conditions that are more frequently associated with IPV (eg, chronic pain, multiple ED visits, STIs, unintended pregnancy, mental health issues such as depression, anxiety, PTSD, and suicide, alcohol and drug presentations). Universal screening includes screening those who are asymptomatic.

The Institute of Medicine has recommended screening for IPV as a preventive health measure, and the USPSTF has recommended routine screening of asymptomatic women of childbearing age for IPV in the health care setting, with referral to intervention services, and the American College of Emergency Physicians has endorsed assessing for family violence in all forms. The USPSTF’s recommendation has a B grade, indicating that there is high certainty that the net benefit is moderate to substantial and there is little evidence of harm, based on a systematic review. Although studies have shown an increase in identification, proving a decrease in violence and increase in quality of life is challenging. A systematic review has found evidence of benefit from screening in certain populations. The task force does not indicate where this screening should happen, but given that survivors use the ED at high rates, and IPV is often missed, the ED seems an appropriate place to screen. Screening in the ED has been found to be safe. When surveyed in the ED, 26% of women in a past-year relationship screened positive and, at follow-up in 1 week and 3 months, there was no report of increased violence or harm as a result of screening.

Although many authorities have recommended screening for IPV, and screening has been found to be acceptable to patients, barriers to screening have been identified, such as time constraints, lack of institutional protocols, policies, and procedures for screening, and negative attitudes and perceptions. Screening is often included in the triage section of the medical record and is often performed by a nurse in a hectic and sometimes public triage area. This approach puts privacy and security at risk because IPV survivors may be accompanied by their abusive partner. This approach also precludes developing a rapport with the provider, an important catalyst for disclosure. Providers should further question intoxicated patients after they are sober, because patients who present with alcohol and drug misuse are less likely to be screened on presentation due to their altered level of consciousness.

Some examples of validated IPV screening tools are presented in Table 59.1. Triage screening should be followed up privately, after all visitors have been asked to step out of the room. When asking about IPV, framing statements are helpful to normalize and destigmatize IPV. Such statements may include the following:

- “Because violence is so common in the lives of my patients, I ask all patients if they are being hurt or threatened by a current or ex-partner.”
- “I have found that many of my patients experience violence at home, so I like to ask my patients if they feel stress, or feel threatened at home.”

The word “stress” may prompt recall of abuse that may not be perceived as IPV by the patient, but that may represent psychological or sexual abuse. Using inclusive terms such as partner will make those in a same sex or gender nonconforming relationships feel more comfortable about disclosing their situation. The emergency clinician should ask open-ended questions to give patients a chance to tell their story. Data have shown that when emergency clinicians asked at least one additional related question, patients were more likely to disclose abuse. Other methods of screening for IPV include electronic and paper surveys filled out by the patient while in the waiting room. Patient should be informed about state-specific reporting requirements that may accompany disclosure of IPV.

Management

An overview of management and documentation considerations is provided in Table 59.2. ED screening for IPV should be combined with a strong, coordinated, institutional response. This should include ED staff training, development of institution-wide written and easily accessible policies and protocols, and in-person resources, including a social worker with IPV expertise or a domestic violence advocate. Components associated with high provider efficacy in screening include screening protocols, institutional support, initial and ongoing training, and access to IPV expert referrals. A strong, hospital-based IPV response includes systems for screening, provider training and maintenance of skills in identification and immediate response, social services, mental

</table>

health and substance abuse staff knowledgeable about IPV, and specialized IPV intervention programs. For institutions that lack a hospital-based IPV program, partnering with a local domestic violence agency or shelter increases resources and facilitates coordination of care. A tool developed by the Agency for Healthcare Research and Quality is available to assess system readiness. This assesses hospital policies and procedures, physical environment, cultural environment, emergency clinician education, screening and safety assessment, program evaluation and quality improvement, and collaborative agreements.

A trauma-informed approach is critical when working with survivors of IPV. This approach recognizes the effect of past and present trauma on an individual and how this influences her or his care. It emphasizes the strengths of the survivor, rather than emphasizing the traumatic effects, recognizes the unique expertise that the individual has regarding the situation, and determines which interventions are most helpful at a given point in time.

**Intervention**

Once a patient has disclosed IPV, the emergency clinician only needs to follow a few simple steps (Box 59.3). The emergency clinician should do the following: (1) acknowledge the abuse experience, commend the patient for disclosing, and explain how this information will facilitate good medical care; (2) validate the patient’s experience and emphasize that no one deserves to suffer physical, psychological, or sexual abuse; and (3) address the risk of acute danger to the patient or their children, determine readiness to take steps to increase safety, and provide specific means to increase safety. Individualized safety planning is complex and time-consuming and is best done by an experienced social worker or advocate in the ED or at follow up. See Fig. 59.2 for a sample template safety plan that can be used when a social worker or advocate is not immediately available.

Possible management options for patients experiencing IPV may include support groups, legal remedies (eg, orders for protection, custody, pressing charges), shelter placement, or ongoing plans for follow-up with community advocates. A discussion about past strategies and what has been successful can help guide future management. Discussing the scope and consequences of abuse on the patient and his or her children can help the patient decide which actions are most appropriate. Orders for protection have been shown to be effective in decreasing future violence, but also have the potential to increase violence. Abusers who do not have respect for the law or act in public are less likely to respect protection orders. Although survivors may make undesirable decisions, the provider should support the survivor and encourage her or him to continue to speak with health care providers and contact IPV agencies in the future.

If children are present in the home, have experienced violence, or are at risk for becoming targets of violence, the emergency clinician may be mandated by law to report this to child protective services. Reporting to child protective services should be done in collaboration with the patient, explaining that this is done to increase resources to help keep the children safe; such a discussion may mitigate the fears of victims that disclosures of violence in the home would risk loss of custody of the child. A brief discussion about the long-term health effects of violence on children may be helpful.

If the patient has not disclosed, but the emergency clinician suspects IPV, a disclosure should not be forced. It is more
identified factors that were more often correlated with IPV violence leading to homicide and can be used to assess immediate risk for future severe violence and lethality in IPV survivors. The tool is somewhat complex to score and requires familiarity. A self-administered version of this tool is available as a downloadable application on iTunes (Fig. 59.4). A brief, five-item version of this tool (Box 59.4) has been evaluated in an ED population of identified IPV survivors at risk for severe or potentially lethal assault, with a “yes” answer to at least three of the questions as the threshold for high risk (sensitivity, 83%). This five-item tool is important to express concern for the patient, explain how the condition may be related to stress (if this is true), and offer support, community domestic violence resources, and the opportunity to return for assistance.

**Danger Assessment**

Campbell and colleagues have developed a 20-item danger assessment tool (Fig. 59.3) that was developed and validated based on reviews of IPV-related homicides across 11 cities.\(^\text{61}\) This study
CHAPTER 59  Intimate Partner Violence and Abuse

Several risk factors have been associated with increased risk of homicides (murders) of women and men in violent relationships. We cannot predict what will happen in your case, but we would like you to be aware of the danger of homicide in situations of abuse and for you to see how many of the risk factors apply to your situation.

Using the calendar, please mark the approximate dates during the past year when you were abused by your partner or ex-partner. Write on that date how bad the incident was according to the following scale:

1. Slapping, pushing; no injuries and/or lasting pain
2. Punching, kicking; bruises, cuts, and/or continuing pain
3. "Beating up"; severe contusions, burns, broken bones
4. Threat to use weapon; head injury, internal injury, permanent injury
5. Use of weapon; wounds from weapon

(If any of the descriptions for the higher number apply, use the higher number.)

Mark Yes or No for each of the following. ("He" refers to your husband, partner, ex-husband, ex-partner, or whoever is currently physically hurting you.)

1. Has the physical violence increased in severity or frequency over the past year?
2. Does he own a gun?
3. Have you left him after living together during the past year?
   3a. (If you have never lived with him, check here___)
4. Is he unemployed?
5. Has he ever used a weapon against you or threatened you with a lethal weapon?
   (If yes, was the weapon a gun?___)
6. Does he threaten to kill you?
7. Has he avoided being arrested for domestic violence?
8. Do you have a child that is not his?
9. Has he ever forced you to have sex when you did not wish to do so?
10. Does he ever try to choke you?
11. Does he use illegal drugs? By drugs, I mean "uppers" or amphetamines, "meth", speed, angel dust, cocaine, "crack", street drugs or mixtures.
12. Is he an alcoholic or problem drinker?
13. Does he control most or all of your daily activities? For instance: does he tell you who you can be friends with, when you can see your family, how much money you can use, or when you can take the car? (If he tries, but you do not let him, check here: ___)
14. Is he violently and constantly jealous of you? (For instance, does he say "If I can’t have you, no one can.")
15. Have you ever been beaten by him while you were pregnant? (If you have never been pregnant by him, check here: ___)
16. Has he ever threatened or tried to commit suicide?
17. Does he threaten to harm your children?
18. Do you believe he is capable of killing you?
19. Does he follow or spy on you, leave threatening notes or messages, destroy your property, or call you when you don’t want him to?
20. Have you ever threatened or tried to commit suicide?

Total "Yes" Answers

Thank you. Please talk to your nurse, advocate or counselor about what the Danger Assessment means in terms of your situation.

Fig. 59.3. Danger assessment tool.

BOX 59.4

Brief Danger Assessment

1. Has the physical violence increased in frequency or severity over the past 6 months?
2. Has he ever used a weapon or threatened you with a weapon?
3. Do you believe he is capable of killing you?
4. Have you ever been beaten by him while you were pregnant?
5. Is he violently and constantly jealous of you?

Mental Health Screening

Given the increased prevalence of mental health disorders, including depression, anxiety, and suicide in IPV survivors, providers should conduct a brief mental health evaluation. Houry and associates have devised and validated a brief screening tool for use in this population (Fig. 59.5). A score of 4 or higher has a positive predictive value (PPV) of 96% for depression, 84% for PTSD symptoms, and 54% for suicidal ideation.
Privacy and Confidentiality Considerations

Privacy is a concern for many IPV survivors. Any referrals or records should be released only after permission is obtained from the survivor. IPV should not be reported to police without the consent of the survivor unless mandated by law in cases of coexisting child, elder, or disabled abuse or based on state-specific reporting statutes (eg, burns or injuries inflicted by weapons). If reporting is mandated, the provider should make every effort to involve the patient. However, concerns for Health Insurance Portability and Accountability Act (HIPAA) violations do not apply in this circumstance; the privacy rule contains a provision allowing disclosure of protected health information to law enforcement in the case of reporting required by law.

Documentation

When a patient does disclose IPV, documentation in the medical record can help other health care providers and the survivor when seeking legal remedies, such as custody or restraining orders. Medical records are often admitted into a court of law as an exception to the hearsay rule, which states that someone cannot testify about something that someone else said. These statements are accepted because they are often made in the usual course of medical care or when the patient is upset and may have less impetus to fabricate. Patient statements should be documented with quotes whenever possible, or with a preceding statement—“patient states. . . .” Injuries should be described, recording the size or length, type of injury (eg, bruise, incised wound, abrasion), and location. EDs should have protocols for digitally photographing injuries and wounds so that they are obtained consistently, with

**Brief Mental Health Screen**

Feel sad?

0  I do not feel sad.
1  I feel sad.
2  I am sad all of the time and can’t snap out of it.
3  I am so sad or unhappy that I can’t stand it.

Have you experienced a traumatic event (rape, car accident, domestic violence, death in the family, et cetera) in the past year?

0  No
1  Yes

Wish to live

0  I have a medium to strong wish to live.
1  I have a weak wish to live.
2  I have no wish to live.

Wish to die

0  I have no wish to die.
1  I have a weak wish to die.
2  I have a medium to strong wish to die.

Total Score: _______

(A score of 4 or higher considered positive, with the need for further mental health referral.)
adequate quality for legal use. Photographs should follow the rule of 4:1 long-range picture, which includes the face for identification, one medium range, and two close range, and one with and one without a ruler (or an object for comparison, such as a coin). All photographs should be stored in tamper-resistant CDs and labeled with the name of the patient, medical record, date, and signature of the person taking the photograph. The presence of photographs should be documented in the medical record. Referrals should also be recorded in the medical record. The diagnosis of IPV or suspected IPV should be documented for the medical record for possible use in legal proceedings, as well as for purposes of research and epidemiology.

**Intimate Partner Violence Coding and Diagnosis**

International Classification of Diseases (ICD)–10 coding provides increased specificity for the coding of IPV (Table 59.3). New codes added to the primary category allow the provider to include adult maltreatment and neglect. Other codes added include suspected IPV (T codes) and past IPV and counseling (V codes). Similar to ICD-9, ICD-10 also includes E codes, which are used to describe the nature of the cause of the injury—for example, “Who committed the act of violence” (E967.0–E967.9), the nature of the abuse (E960–E968), the intent of the abuse or neglect (E904.0–E968.4), and the intentionality of the abuse (E980–E989).

**DISPOSITION**

Most ED patients with IPV will be treated and discharged. Patients who are victims of potentially life-threatening injuries, particularly attempted strangulation, are at great danger of future violence and should have safe plans for discharge or be offered temporary admission for safety.63 Although shelters are one option, they are an extreme solution, typically removing the survivor from friends and family and sometimes requiring them to leave their place of employment and their children’s school. Furthermore, shelters are not always an available option; they are often full and may not accept patients with substance abuse issues, teenage male children of survivors, or male or transgender survivors.

All survivors who are being discharged should receive resources for domestic violence, mental health, substance abuse, and social services. The emergency clinician may not agree with the choices made by the survivor but should always respect these decisions and offer encouragement and validation. This approach will increase the chances of a positive interaction and increase the likelihood of further help-seeking behavior.

**KEY CONCEPTS**

- Intimate partner violence encompasses a pattern of controlling behaviors, including intentional physical assault, sexual assault, psychological violence, and financial control.
- Treatment and intervention in intimate partner violence may be compared to a chronic disease model, whereby intervention happens over time, and relapses may be a part of the cycle. It is also critical to remember that although intervention is often offered to the survivor, responsibility for the behavior should be placed on the abusive partner.
- Treatment and intervention in IPV requires a coordinated approach, including physician training, an integrated system that includes social work and IPV counselor availability, and a close relationship with area IPV service provider groups.
- Routine screening for IPV in women of childbearing age is recommended by the USPSTF; screening methods may include paper-based, computer-based, face to face (by nurse or physician), or combination of screening methods.
- Sequelae of IPV include chronic pain, mental health issues (eg, depression, PTSD, substance abuse), STIs and unintended pregnancy, and worsening of medical problems (eg, diabetes, asthma).
- Attempted strangulation in IPV is associated with a sevenfold increased risk of an attempted or completed lethal attack, and patients should be encouraged to seek protection from further incidents.
- Some cases of IPV presenting to the ED may actually be cases of human trafficking. Cases of human trafficking have a very different dynamic and require specialized interventions.

CHAPTER 59: QUESTIONS & ANSWERS

59.1. By state law, you are a mandated reporter for intimate partner violence (IPV). You are concerned about violating the Health Insurance Portability and Accountability Act (HIPAA). Which of the following is correct?
   A. Patients are always free to act of their own free will.
   B. Reporting should be done without telling the patient, because you cannot report if the patient objects.
   C. When reporting is required by law, it does not require patient consent.
   D. You need a signed consent to make the report.
   E. You should call the legal department before reporting.

**Answer:** C. IPV patients are not always free to act of their own will in health care decision making. Some states have laws that require reporting to local authorities. Reporting of health conditions required by local laws are exempted from HIPAA regulations. Fear may be so profound in the IPV survivor that decision making is impaired, thus jeopardizing informed consent.

59.2. Which of the following is not suspicious for intentional injury from IPV?
   A. Bilateral injuries
   B. Ecchymosis of lower extremity
   C. Injuries to the breasts or abdomen
   D. Injuries to the hands and extensor surface of the forearms
   E. Pattern injuries

**Answer:** B. Signs of an intentional injury include a central location (ie, trunk and breasts), bilateral injuries (both arms or both legs), defensive injuries (ie, ecchymoses on the back of the hand as a result of protecting the face), and patterned injuries (having the markings of an object, such as the sole of a shoe or a burn with the imprint of an iron).

59.3. Which of the following about a woman should alert the provider that the patient may be a victim of human trafficking, rather than IPV?
   A. Appears much younger than her stated age and does have not identification with her
   B. Is accompanied by her partner who will not leave her side
   C. Is easily startled
   D. Is evasive in answering questions about her injuries
   E. Presents with a traumatic injury at night

**Answer:** A. Most of these situations apply to the IPV survivor and victim of human trafficking. Presentations that should alert the provider that the patient may be a victim of human trafficking rather than IPV include a person who looks much younger than her stated age (she often is younger). Other clues include a victim that does not have identification papers (the “employer” often takes these from the victims under the guise of “keeping the documents safe”), but this also prevents the victim from leaving without these documents. Untreated sexually transmitted infections (STIs, including pelvic inflammatory disease), malnourishment, and addiction to drugs and alcohol. It is important for the provider to consider the presentations of human trafficking, because although the victim may not be identified in the ED—for a number of reasons, including lack of trust and familiarity with the ED provider, the resources that may be helpful are somewhat different than those used by IPV survivors.

59.4. Key management steps after identifying a patient experiencing IPV include which of the following?
   A. Creating a detailed and comprehensive safety plan
   B. Emphasizing the importance of leaving the abuser immediately
   C. Keeping the patient in the ED until she agrees to contact police and have a restraining order issued
   D. Providing validation about disclosing the abuse
   E. Reinforcing the importance of secrecy about the abuse until the woman has left the home

**Answer:** D. Emergency clinicians should validate the disclosure of abuse, emphasize that the victim is not at fault, and encourage future discussions with IPV community agencies or other health care providers. Immediate safety should be assessed, but most patients will not want to leave the abuser immediately; however, a positive initial conversation may begin the process of ending the abusive relationship. A templated list will allow the ED staff to create a basic safety plan with the patient; an individualized plan is best done in conjunction with trained domestic violence advocates, typically in follow-up.
INTRODUCTION

Dental concerns are a common chief complaint in the emergency department (ED). The spectrum of oral disease ranges from bothersome to emergently life-threatening. This chapter covers disorders of the tooth, gingiva and periodontium, dental procedure-related issues, odontogenic and deep infections of the head and neck, traumatic dental emergencies, as well as temporomandibular joint disorder (TMD) and dislocation.

Principles

Anatomy

Humans have 20 deciduous (primary) teeth and 32 permanent (secondary) teeth, which are supported and maintained in the maxilla (upper teeth) and mandible (lower teeth) by the periodontium. The tooth that is normally visible in the mouth is considered the crown, whereas the tooth that is under the gingival line is the root (Fig. 60.1).

The crown of the tooth has three layers; from outside to inside they are the enamel, dentin, and pulp. The enamel is the only part of the tooth that is visible in the absence of pathology (eg, fractures, caries) and is a hard coating that protects the tooth. The next layer deep to the enamel is the dentin, which is an intermediate layer between the enamel and the pulp (for the crown) and between the cementum and the pulp (for the root). Yellow in appearance, dentin is comprised of porous microtubules, supports the enamel, and acts as a cushion during mastication. If dentin is exposed from caries or trauma, the patient will have tooth sensitivity and/or pain. The deepest layer is the pulp cavity, which houses the neurovascular supply.

The normal primary, or deciduous, dentition (“baby teeth”) consists of 10 mandibular and 10 maxillary teeth (Fig. 60.2). The lower central incisor is the first tooth to erupt at approximately 6 months of age; all primary teeth should be present by 3 years of age. The permanent dentition begins to erupt at approximately 5 to 6 years of age with the appearance of the first molar.

The permanent dentition consists of 32 teeth; there are 8 teeth per quadrant (eg, right upper, right lower, left upper, left lower). From medial to lateral, the names of the teeth in each quadrant are: the central incisor, lateral incisor, canine, two premolars (also called bicuspids), and three molars (also called tricuspids). The third molars (“wisdom teeth”) are the last to erupt, appearing at approximately 16 to 18 years of age. The permanent dentition are numbered from 1 to 32, starting with the upper right third molar (1) and moving to the upper left third molar (16), to the lower left third molar (17), and to the lower right third molar (32). The starting point for this numbering system can be recalled by the mnemonic “upright.” It is often easier to name the tooth or teeth involved; for instance, if tooth 8 is injured, the clinician could describe the tooth as the “right maxillary central incisor” or the “right upper central incisor.” If multiple teeth are involved, numbering is more concise.

Specific terminology is also used to describe the various surfaces in the mouth. The facial (also referred to as labial or buccal) surface faces outside the oral cavity; the oral (also referred to as palatal for upper teeth, or lingual for lower teeth) surface faces the tongue; the mesial surface is toward the midline; and the distal surface is toward the ramus of the mandible. The interproximal surface refers to the contacting area of adjacent teeth, and the occlusal surface refers to the biting area. Finally, apical is in the direction of the root, whereas coronal is toward the crown of the tooth.

Pathophysiology

Dental caries are caused by breakdown of the teeth secondary to bacterial activity. Bacteria generate acid as a byproduct from cellular metabolism of food left on the tooth surface, subsequently demineralizing the enamel. Once the enamel is breached, the microporous dentin is able to transmit saliva, byproducts of the bacteria, and the bacteria to the pulp. The pulp initially reacts with a hyperemic response, which continues to an inflammatory state termed pulpitis, which can be reversed. Untreated, pulpitis can further progress to total degeneration and necrosis (irreversible pulpitis).

Cracked tooth syndrome (CTS) is a condition that generally affects adults 30 to 60 years old and is defined as “a fracture plane of unknown depth and direction passing through tooth structure that may progress to communicate with the pulp and/or periodontal ligament.” These fractures can occur due to either excessive forces on a normal tooth (eg, accidentally biting on a hard object, such as metal or bone), or normal forces on a weakened tooth (eg, a carious tooth or one that has undergone dental procedures previously). Because of the mechanism of injury, teeth subjected to larger forces (such as the mandibular molars) are most commonly affected. If misdiagnosed, the fracture may propagate into the pulp or periodontal ligament and compromise viability of the tooth.

Clinical Features

Dental caries is the most common cause of odontogenic pain. The patient may give a variable history of a sudden or gradual onset of a sharp to dull, throbbing pain. In most cases, the patient can...
indicate the specific tooth involved, but pain may be generalized. Early (reversible) pulpitis is sensitive to changes in temperature and pressure; irreversible pulpitis can have pain without any stimulus.

CTS patients may provide a history of preexisting dental procedures or disease, or they may have a history of occlusive trauma. Presenting symptoms are similar to those of dental caries.

**Physical Examination**

The physical examination described here is applicable to all sections of this chapter. Ideally the patient should be placed in a dental or ear, nose, and throat chair or on a bed at a 45-degree angle with adequate lighting. Pediatric patients often are examined while sitting in the parent’s lap.

Pediatric patients may require anxiolysis or sedation to permit adequate oral assessment and treatment of a painful condition. Pediatric procedural sedation is described in Chapter 162.

A complete examination includes inspection of the oral cavity, gingiva, teeth, and surrounding structures (e.g., throat, neck, sinuses) if indicated. Assess teeth for caries or cracks. Localization of the involved tooth may be accomplished by percuting the teeth or by having the patient bite on a tongue blade. Exquisite pain to percussion suggests an underlying periapical abscess (discussed in the section Odontogenic and Deep Neck Infections).

Examine the nares and sinuses for discharge and pain, respectively, to evaluate for sinusitis. Palpate the temporomandibular joint (TMJ) with opening and closing of the jaw to assess for “clicks” or “pops,” which may indicate the etiology of pain as TMJ disorder. In older individuals, palpate the temporal artery for tenderness and prominence.

**Differential Diagnoses**

Most dental pain in the ED is odontogenic, the most common being pulpitis due to caries. Tooth pain is not always odontogenic, however. Unilateral upper tooth pain (usually the posterior teeth) can be related to maxillary sinus dysbarism or inflammation. Trigeminal neuralgia can present as tooth pain, but it is usually lancinating and may not be related to temperature changes or mastication (see Chapter 95). Atypical odontalgia is a centralized trigeminal neuropathy localized in a tooth or teeth. Frequently-misdiagnosed, patients will often undergo multiple dental procedures with worsening of their pain. Atypical odontalgia causes persistent throbbing or burning pain that does not fulfill diagnostic criteria for another disorder and therefore is a diagnosis of exclusion.

Older patients with temporal (giant cell) arteritis may have pain with mastication because of jaw claudication.

**Diagnostic Testing**

No laboratory or radiographic testing is routinely indicated.

**Management**

Management of dental caries with pulpitis and CTS is aimed at treating the patient’s pain and referring to a dentist for definitive care.

Severe pain can be treated with supraperiosteal infiltration of local anesthetic to provide temporary relief (Fig. 60.3). To perform this, dry the area with gauze, apply a topical anesthetic to the gingiva (e.g., 20% benzocaine or 5% lidocaine) and allow it to sit for 5 minutes. Inject 1 to 2 mL of local anesthetic (e.g., 2% lidocaine) through the mucobuccal fold of the affected tooth with the bevel facing the tooth. Alternatively, an inferior alveolar nerve block may be used when multiple lower teeth are affected on one side.

The patient can be discharged with ibuprofen 400 to 600 mg tablets every 4 to 6 hours. Nonsteroidal antiinflammatory drugs (NSAIDs) given at scheduled times (rather than as needed) are more effective than opioid analgesics for these conditions. However, for severe odontalgia, a short course of opioid analgesics in addition to scheduled NSAID administration is reasonable. Opioid analgesics should not be prescribed for long-standing dental problems, such as well-established caries.

**Disposition**

The patient with odontalgia from dental caries or CTS should follow-up with a dentist within the week. Those with CTS should be instructed to avoid chewing on the affected side to avoid further trauma and fracture propagation.
Principles

Anatomy

The periodontium serves to hold the teeth in place, as well as protect the root from bacteria. Surrounding the root of the tooth instead of enamel is cementum, which helps fix the tooth to the alveolar bone by attaching to the periodontal ligaments. Collectively, the periodontal ligament, alveolar bone, and cementum comprise the attachment apparatus. The attachment apparatus plus the gingiva (“gums”) is referred to as the periodontium. The gingiva consists of the mucosal tissue that overlies the mandible and maxilla inside the mouth and, in the normal state, acts as a barrier to infection and injury.

Pathophysiology

Gingivitis and Periodontitis. Periodontitis is inflammation of the supporting structures of the teeth (gingiva, alveolar bone, cementum, periodontal ligament). Degradation of the support structure leads to loss of alveolar bone and subsequent loosening or loss of teeth.

In necrotizing periodontal diseases, polymicrobial bacteria (with a predominance of Fusobacterium and spirochetes) invade the tissue and cause pain, bleeding, and destruction. These diseases include necrotizing gingivitis (acute necrotizing ulcerative gingivitis [ANUG], or “trench mouth”) if only the gingiva are involved, necrotizing periodontitis if the attachment apparatus in addition to the gingiva is involved, and necrotizing stomatitis if the disease further extends into the surrounding oral mucosa (Fig. 60.4). Infection of the tonsils and pharynx is termed Vincent’s angina. The most diffuse necrotizing disease is termed noma (cancrum oris, fusospirochetal gangrene) where the entire mouth is involved and is often fatal; this disease is most commonly encountered in young children in developing countries (Fig. 60.5).

Pericoronitis. The gingiva and surrounding tissue can also become inflamed due to a condition known as pericoronitis. As teeth start to erupt, debris and bacteria can accumulate between
the tooth and the surrounding soft tissue (this “gum flap” overlying the tooth is called the operculum; Fig. 60.6). The third molar (“wisdom tooth”) is most commonly implicated, and symptoms typically occur in the second or third decade of life. This condition is more common with teeth that are malerupted or impacted. As the tissue becomes enlarged due to inflammation, the problem is worsened by trauma to the area during mastication.

**Gingival Hyperplasia.** Gingival hyperplasia can occur secondary to medications. The most commonly-associated drug classes are anticonvulsants, calcium channel blockers, and immunosuppressants (Table 60.1).

**Clinical Features**

**Historical Features**

The presentation of periodontitis is variable, depending on the severity of the disease. Simple gingivitis presents with complaints.
of swollen gingiva that are tender, gingival bleeding after manipulation (eg, brushing teeth, flossing), and halitosis from bacterial overgrowth. Periodontitis involves the attachment apparatus as well; therefore, patients often will have the aforementioned symptoms but in addition may have gingival recession from loss of alveolar bone and concomitant teeth loosening. Individuals with more severe periodontitis may also report fevers and malaise. A medication history should be obtained to assess for drug-induced gingival overgrowth.

Physical Examination
The gingiva should be inspected for erythema, edema, and hyperplasia. Gingivitis is typically painless but will show inflammation, edema, and bleeding with probing. The interdental papillae should normally be pointed but, in necrotizing disease, the interdental papillae become blunted, “punched out,” ulcerated, and covered with a whitish-yellow pseudomembrane of necrotic tissue and bacteria. The triad for necrotizing periodontal diseases includes papillary necrosis, gingival bleeding, and pain. More severe infection (eg, necrotizing stomatitis) may also have associated submandibular lymphadenopathy.

Mobile teeth suggest alveolar bone loss, where the disease has progressed deeper than the gingiva. Partially-erupted teeth should be examined for evidence of pericoronitis. The overlying tissue (operculum) should be assessed for bleeding and inflammation.

Differential Diagnosis
Ulceration of the mucosa can be caused by necrotizing stomatitis but also by aphthous ulcers and other oral lesions. Aphthous ulcers are 2 to 3 mm in diameter and have a whitish center and are tender, but they usually do not become infected. The neighboring gingiva should not be affected and appear healthy. Recurrent aphthous lesions can occur with Behçet disease and human immunodeficiency virus (HIV). Treatment is symptomatic with hydroxycarbon rinses and topical anesthetics. Another consideration is acute herpetic gingivostomatitis, which is the most common manifestation of primary herpes simplex virus infection in children. For patients with gingival hyperplasia, an infiltrative process (such as, leukemia) should be considered, especially if the patient is not on any medications associated with hyperplasia.

Diagnostic Testing
Necrotizing periodontal disease occurs most often in patients with diabetes, and those who are immunocompromised, such as patients with HIV or long-term immunosuppressive therapy. Blood glucose and HIV testing may be initiated in the ED or as part of follow-up.

Management
Gingivitis and Periodontitis
Gingivitis will respond to proper oral hygiene, and the patient should be instructed on twice daily flossing and brushing. Antibacterial mouth rinses should be prescribed if the gingivitis is severe: either chlorhexidine rinses (preferred agent, 0.12% to 0.2%) or 3% hydrogen peroxide (diluted 1:1 with warm water) should be performed twice daily. Necrotizing periodontal disease should be treated by a dentist, who will need to debride the necrotic tissue. Oral antimicrobials should be prescribed for patients with extensive disease or systemic effects; see Table 60.2 for suggestions.

All patients who smoke should be counseled on smoking cessation; this is the most common risk factor in HIV-negative patients. Analgesia with an NSAID or acetaminophen relieves pain and facilitates appropriate oral hygiene, because periodontal conditions are painful. Opioid analgesics rarely are needed. Topical analgesics (eg, viscous lidocaine) can also be effective, but should be applied only to small areas; patients must be cautioned about targeted use to avoid local anesthetic toxicity.

Pericoronitis
Patients with pericoronitis should receive rinses as described for periodontal disease; systemic antibiotics are not necessary unless the pericoronitis is severe. In such cases, antibiotics are as described for periodontal disease. Patients with pericoronitis should be referred to dentist or oral surgeon for local treatment of the operculum or, if impacted or malerupting, removal of the tooth.

Disposition
Patients with gingivitis are discharged with dental follow-up in 1 to 2 weeks. Those with necrotizing gingivitis or mild necrotizing stomatitis should see a dentist within 24 to 72 hours, because they require frequent debridement until the infection is controlled. Patients with severe necrotizing stomatitis or gingivitis should have emergency dental consultation (within 24 hours). Patients with significant systemic symptoms (especially fever), those who are immunocompromised with severe oral disease, and those who are unable to adequately hydrate because of mouth pain are admitted to hospital or placed in an observation unit for intravenous (IV) hydration, analgesia, and dental or oral medicine consultation.

DISORDERS INVOLVING DENTAL PROCEDURES

Principles

Anatomy

The most common dental procedures include fillings, crowns, root canals, and extractions. Fillings cover cavities and protect the underlying tooth from further decay and infection. Crowns (or “caps”) cover the portion of the tooth exposed above the gingiva and require an intact root for attachment. Root canals involve opening the pulp chamber, removing pulp tissue and root, sterilizing the canal, and sealing it to prevent ingress of saliva and contamination. Extractions are performed for non-salvageable teeth and involve removal of the entire tooth. All of these procedures can have complications that may bring a patient to the ED.

Pathophysiology

Dislodgement of a filling or crown can expose the highly-innervated pulp and lead to significant odontalgia. Similarly, the pulp can be irritated during procedures that involve the pulp (eg, root canal) because of residual gas bubbles that are inadvertently sealed into the cavity. In addition, any swelling that may elevate the tooth even minimally post-procedurally will cause premature and painful contact during mastication.

After an extraction, the patient will have an adherent clot in the fossa where the root of the tooth previously was. If this clot becomes dislodged (typically 3 to 4 days post-extraction) a condition called alveolar osteitis (“dry socket”) can occur (Fig. 60.7). The incidence of alveolar osteitis is 2% after routine extraction but as high as 20% to 30% after removal of impacted mandibular third molars. The pain is secondary to localized inflammation of the now-exposed surrounding alveolar bone.

Clinical Features

Historical Features

Patients usually can provide the history of their dental procedures; dislodgement of a filling or crown can happen at any time but is more common early or with trauma. Post-root canal pain due to retained gas bubbles typically occurs immediately after the initial nerve block wears off.

Fig. 60.7. Alveolar osteitis (“dry socket”) with extraction site devoid of clot. (From Krakowiak PA: Alveolar osteitis and osteomyelitis of the jaws. Oral Maxillofac Surg Clin North Am 23[3]:401–413, 2011, Fig. 1.)

Alveolar osteitis characteristically presents 3 to 4 days after an extraction with severe dull, aching pain at the site of extraction, which is often associated with halitosis and a foul taste in the mouth. They may have an antecedent history of sucking through a straw or other activity that dislodged the clot.

Those with continued bleeding after an extraction should have their medical history and medications reviewed with specific attention to coagulopathies, such as hemophilia, as well as medications, such as anticoagulants, including anti-platelet agents.

Physical Examination

Patients with dislodged fillings or crowns will have exposed dentin or pulp over the affected teeth. Post-extraction pain secondary to inflammation or retained gas bubbles may have a normal examination. Those with alveolar osteitis will have a tooth socket that has at least partial loss of the blood clot with exposed bone.

Diagnostic Testing

An international normalized ratio (INR) is indicated for patients who are on warfarin and have post-extraction bleeding.

Management

For teeth with exposed pulp, calcium hydroxide cement (Dycal) application to cover the exposed surface may provide symptomatic relief. If the patient has a loose or displaced crown, the crown itself can be reimplanted if the tooth surface is clean; place the calcium hydroxide cement and ask the patient to bite down. Analgesia with NSAIDs is generally sufficient. For those with severe pain and objective findings, a short course (2 to 3 days) of an opioid can be prescribed. Patients with retained gas bubbles after a root canal have intense pressure-like pain, often refractory to analgesics and even nerve blocks, and they should be referred to an endodontist, preferably the clinician who performed the initial procedure.

Patients with alveolar osteitis should receive NSAID analgesia and have prompt (next working day) consultation by their treating oral surgeon. If follow-up will be delayed, nerve block followed by gentle irrigation of the socket with sterile saline can be performed. The socket should not be curetted and the clot should not be removed if residual clot exists, because this will expose more bone and lead to higher risk of continued pain and osteomyelitis. Medicated iodoform gauze with eugenol (an anesthetic) can be placed in the cavity and changed by the patient’s surgeon within 24 to 48 hours with repeat irrigation. No other treatment for alveolar osteitis has enough evidence to recommend use.

Extraction site bleeding should first be managed with direct pressure with the patient biting on dry gauze. If this fails, perform a supraperiosteal nerve block with lidocaine with epinephrine, because this will decrease blood supply as well as anesthetize the area so that more firm direct pressure can be applied. Repeat the direct pressure. If bleeding continues after a second trial of pressure, the socket should be packed with absorbable gelatin sponge (Gelfoam) with or without topical thrombin. The gingiva can also be loosely closed with a 3-0 absorbable suture in a figure-of-eight fashion. If there is significant ongoing hemorrhage that will not respond to local measures, reversal of anticoagulation may be undertaken in consultation with the patient’s cardiologist (see Chapter 114).

Disposition

In the absence of infection and with control of bleeding, patients with dental procedure-related complications can be discharged
Neck infections. An overview of the anatomy relevant to the discussion is presented in Fig. 60.8.

There are two primary spaces that can be involved with maxillary deep neck infections: the canine and buccal space. Infections of the root of the maxillary canine can lead to a canine space infection and often present with flattening of the ipsilateral nasolabial fold (Fig. 60.9). The major complication of this type of infection is cavernous sinus thrombosis. The buccal (buccinator) space can be involved with maxillary molars but also with mandibular molars (Fig. 60.10). Occasionally, the maxillary sinus itself can be involved.

The mandible has three associated primary spaces: submental, sublingual, and submandibular. The submental space is bound laterally by the digastric muscles and therefore causes a very discrete midline swelling when involved in a deep neck infection (Fig. 60.11); the mandibular incisors are the main culprits, because other teeth do not overly this space. The sublingual space is

**ODONTOGENIC AND DEEP NECK INFECTIONS**

**Principles**

**Anatomy**

The anatomy of the neck is complex and comprises multiple true and potential spaces. There are fascial planes that normally act to contain infection; with aggressive organisms, an immunocompromised state, or surgical breech of these planes, further extension can occur. For odontogenic infections, these spaces can be divided into those involved with maxillary infections and those involved with mandibular infections. More severe infections of the head and neck (such as, those involving these spaces) are called deep neck infections. An overview of the anatomy relevant to the discussion is presented in Fig. 60.8.

There are two primary spaces that can be involved with maxillary deep neck infections: the canine and buccal space. Infections of the root of the maxillary canine can lead to a canine space infection and often present with flattening of the ipsilateral nasolabial fold (Fig. 60.9). The major complication of this type of infection is cavernous sinus thrombosis. The buccal (buccinator) space can be involved with maxillary molars but also with mandibular molars (Fig. 60.10). Occasionally, the maxillary sinus itself can be involved.

The mandible has three associated primary spaces: submental, sublingual, and submandibular. The submental space is bound laterally by the digastric muscles and therefore causes a very discrete midline swelling when involved in a deep neck infection (Fig. 60.11); the mandibular incisors are the main culprits, because other teeth do not overly this space. The sublingual space is

---

**Fig. 60.8.** Anatomy of maxillofacial space infections. (From Bagheri SC: Clinical review of oral and maxillofacial surgery, ed 2, St Louis, 2013, Elsevier/Mosby, Fig. 4.4.)
between the floor of the mouth and the mylohyoid muscle, but it does not have a posterior border and therefore communicates with the submandibular space. Characteristically, infection of this space causes elevation of the tongue and firmness of the floor of the mouth (Fig. 60.12). Lastly, the submandibular space is usually involved as an extension of infection from a mandibular molar (Fig. 60.13). Although submandibular space infections have their medial border at the anterior belly of the digastric muscle, it can easily bypass this and enter the submental space and move to the contralateral submandibular space, as well as the sublingual space (because there is no posterior boundary); this leads to infection of all three spaces and causes Ludwig angina.

These primary space infections can progress to secondary spaces and lead to more wide-spread infection into the neck and mediastinum. A discussion of these spaces (e.g., retropharyngeal, parapharyngeal, prevertebral, and “danger” spaces) can be found in Chapter 65.

Pathophysiology

Oropharyngeal infections are the most common cause of deep neck infections in children (Fig. 60.14, Scenario 1 and 2). Acute tonsillitis can lead to peritonsillar abscesses and, if further invasion of the parapharyngeal space occurs, can spread into either the retropharyngeal (leading to a retropharyngeal abscess) or submandibular space (potentially leading to Ludwig angina). Children can have retropharyngeal lymphadenopathy with pharyngeal and/or sinus infections, which can lead to retropharyngeal cellulitis, lymphadenitis, or abscess. By age 4, there is spontaneous atrophy of these nodes; therefore, a retropharyngeal abscess in the absence of trauma (esophagogastroduodenoscopy [EGD], bone stuck in

![Fig. 60.9](image1). Left canine space infection. (From Lypka M, Hammoudeh J: Dentoalveolar infections. Oral Maxillofac Surg Clin North Am 23[3]:415–424, 2011.)

![Fig. 60.11](image3). Submental space infection with characteristic discrete midline swelling. (From Flynn TR: Complex odontogenic infections. In Hupp JR, Ellis E, Tucker MR: Contemporary oral and maxillofacial surgery, ed 6, St Louis, 2014, Elsevier/Mosby, pp 319–338.)
for the infection, although a mixed staphylococcal-streptococcal flora is common, and both may lead to an overgrowth of anaerobic gas-producing organisms, including *Bacteroides fragilis*.

Facial cellulitis is typically polymicrobial with a predominance of anaerobes, which reflects typical oropharyngeal flora. However, atypical organisms can also be present: Actinomyces can cause cervicofacial actinomycosis with draining sinus tracts, tuberculosis can cause cervical lymphadenopathy (scrofula) with secondary infection, and *Bartonella henselae* (the causative organism for cat scratch disease) can cause cervical lymphadenitis.

**Clinical Features**

**Historical Features**

Facial cellulitis and deep neck infections have many common historical features: in children, an antecedent sinus or pharyngeal infection is common; in adults, a history of poor dentition is common. Frequently-reported symptoms include pain at the affected site, fever, and malaise.

Recent dental work or trauma, recent upper airway manipulation or surgery, intravenous (IV) drug abuse, sinusitis, and throat, and so on) in older children or adults is rare. Another complication of oropharyngeal infections is septic thrombophlebitis of the internal jugular vein, termed *Lemierre syndrome*, and is most frequently secondary to *Fusobacterium necrophorum*. Septic emboli dislodge from the internal jugular vein and lead to necrotic pleuropulmonary emboli, abscesses, and empyema. More distant embolic events can occur, leading to brain abscesses, meningitis, and septic joints.

Dental infections are the most common cause of deep neck infections in adults (see Fig. 60.14, Scenario 3). Pus can leak from the apex of an infected tooth root and form a periapical abscess, confined within the alveolar bone (Fig. 60.15). The abscess may break through the cortical plate of either the mandible or the maxilla and spread subperiosteally, extending into the previously-described spaces. When the submental, submandibular, and sublingual spaces are involved with cellulitis with or without abscess, Ludwig angina occurs. Ludwig angina is a bilateral, boardlike swelling involving the submandibular, submental, and sublingual spaces with elevation of the tongue (Fig. 60.16). The most serious immediate sequelae is airway obstruction. A characteristic brawny induration is present; there is no fluctuance for incision and drainage. Hemolytic Streptococcus is most commonly responsible for the infection, although a mixed staphylococcal-streptococcal flora is common, and both may lead to an overgrowth of anaerobic gas-producing organisms, including *Bacteroides fragilis*.

Facial cellulitis is typically polymicrobial with a predominance of anaerobes, which reflects typical oropharyngeal flora. However, atypical organisms can also be present: Actinomyces can cause cervicofacial actinomycosis with draining sinus tracts, tuberculosis can cause cervical lymphadenopathy (scrofula) with secondary infection, and *Bartonella henselae* (the causative organism for cat scratch disease) can cause cervical lymphadenitis.

**Clinical Features**

**Historical Features**

Facial cellulitis and deep neck infections have many common historical features: in children, an antecedent sinus or pharyngeal infection is common; in adults, a history of poor dentition is common. Frequently-reported symptoms include pain at the affected site, fever, and malaise.

Recent dental work or trauma, recent upper airway manipulation or surgery, intravenous (IV) drug abuse, sinusitis, and
**Fig. 60.14.** Common routes of spread in deep neck infections. (Modified from Cummings CW, Flint PW, Harker LA: Cummings otolaryngology head & neck surgery, ed 4, St Louis, 2004, Elsevier/Mosby, Fig. 10.2.)

**Fig. 60.15.** A, Periapical abscess diagram. B, Physical examination findings of a periapical abscess. (From Buttaravoli P, Leffler SM: Minor emergencies, ed 3, St Louis, 2012, Elsevier, pp 178–180, Figs. 45.3 and 45.4.)
because it is not relieved with neuromuscular blockade. Difficulty swallowing or handling secretions suggests the possibility of retropharyngeal or parapharyngeal infection. Respiratory distress may be apparent, or the airway may occlude rapidly after a period of minimal signs of impending obstruction.

Diagnostic Testing
A complete blood count usually shows leukocytosis, but the absence of such does not rule out a deep neck infection or significant cellulitis. The imaging modality of choice is a computed tomography (CT) of the face (and, if clinically indicated, the neck as well) with IV contrast (if not contraindicated). The physical examination may be inaccurate in correctly determining the extent of an infection, and CT is required to delineate the infection and to ascertain its effects on adjacent structures (eg, the airway). Patients with HIV have an increased risk of deep neck infections, and HIV testing may be helpful for patients not known to have HIV and not recently tested.9

Physical Examination
A complete head and neck examination is required, keeping in mind the aforementioned anatomy. Extraoral palpation can help assess whether there is deep space involvement; presence or absence of tenderness, warmth, fluctuance, and crepitus should be evaluated. The quality of dentition should be assessed and any concerning areas should be percussed for tenderness, which may indicate a periapical abscess. The floor of the mouth should be evaluated to see if the sublingual space is involved.

Irritation of the internal pterygoid or masseter muscles causes trismus, which is the inability to open the mouth because of involuntary muscle spasm. Trismus limits the ability to perform a complete oral examination; it will also make intubation difficult because it is not relieved with neuromuscular blockade. Difficulty swallowing or handling secretions suggests the possibility of retropharyngeal or parapharyngeal infection. Respiratory distress may be apparent, or the airway may occlude rapidly after a period of minimal signs of impending obstruction.

Management

Well-appearing patients with simple odontogenic infections (localized infection, no recent antibiotics, and an immunocompetent patient) can be managed with antibiotics as shown in Table 60.2. Simple tooth abscess can be drained with local incision under local anesthesia if the clinician is skilled in the procedure. A 3-day course of antibiotics is as effective as a 5- or 7-day course of antibiotics after drainage of a localized dentoalveolar abscess if the patient has systemic symptoms. In the absence of systemic symptoms, routine antibiotics are unnecessary after successful drainage of a periapical abscess. 1

Most abscesses are drained by dentists or oral surgeons and tooth extraction may be required. Oral or maxillofacial surgery consultation is advisable before drainage of suspected deeply-seated abscesses.

All serious deep neck infections should have broad-spectrum IV antibiotics administered. We recommend ampicillin-sulbactam with vancomycin or, if allergic to penicillin, clindamycin monotherapy in the immunocompetent host. See Table 60.3 for further details regarding antibiotic therapy in deep neck infection.

Ludwig angina management consists of antibiotics and airway management. Oral intubation may be difficult because of inability to displace the tongue with a laryngoscope. Intubation is not generally emergent and can be done in the operating room. Examination of the glottis and supraglottic airway by flexible endoscopy will ascertain the degree of airway compromise and, hence, the urgency of airway management. When emergent intubation is indicated, or a patient requires intubation before a prolonged transfer for care, we recommend use of a videolaryngoscope or flexible intubating endoscope (see Chapter 1). Consultation with an oral maxillofacial surgeon or otolaryngologist is indicated.

Disposition

Those with simple odontogenic infections can be discharged with close outpatient follow-up; more severe odontogenic infections, systemic toxicity, or immunocompromised patients should be admitted. Deep neck infections should be admitted. Those with concern for airway compromise (eg, Ludwig angina) or with extension into the neck or mediastinum should be admitted to the intensive care unit (ICU) after thorough evaluation of the airway by CT, flexible endoscopy, or both.

DENTOALVEOLAR TRAUMA

Principles

Anatomy

Dentoalveolar trauma is common complaint and can involve any tooth. The maxillary central incisors are commonly-involved because many children have an anterior overbite, predisposing these teeth to injury. When teeth are subject to trauma, they can become concussed (with pain to percussion), subluxed (whereby teeth become more mobile, but are in their normal anatomic position), luxed (moved from their anatomic position), avulsed (out of the socket), or fractured. Refer to the first section of this chapter to review the relevant dental anatomy.

Pathophysiology

Dental Fractures. Forces that are applied to a tooth can lead to fractures. Fracture classification is important, because it guides management. When a fracture only involves the enamel, it is termed an Ellis class I; when a fracture involves the enamel and dentin, it is termed an Ellis class II; when a fracture involves the enamel, dentin, and pulp, it is termed an Ellis class III (Fig. 60.17). It is appropriate to name the fracture either anatomically (eg, a fracture of the right maxillary central incisor involving the enamel and dentin) or by Ellis classification (eg, an Ellis class II fracture of the right maxillary central incisor). Some practitioners are unfamiliar with the Ellis classification, but an anatomic description is always understood and is therefore probably preferred. The presence of dentin can be ascertained by seeing the yellow tint of the dentin through the fracture. Fractures involving the pulp have a pinkish tinge or have a small amount of visible blood.

Concussion, Subluxation, Luxation, and Avulsion. Concussion occurs when the periodontal ligament sustains a mild injury, causing tooth pain but no mobility. More severe injuries include subluxation or luxation. If a tooth is mobile but is in the correct anatomic position, it is subluxed and will heal as long as no further trauma occurs. Luxation is where the tooth itself is moved in any direction that is no longer anatomic, and it can be further divided into four types: (1) extrusive luxation is where the tooth is forced partially out of the socket in an axial direction, (2) intrusive luxation occurs when a tooth moves apically (and can be mistaken for an avulsion if completely intrusively luxated), (3) laterally luxed, where the tooth is displaced laterally with potential surrounding alveolar bone injury, and (4) avulsion where the tooth is completely out of the socket (Fig. 60.18). A long-term sequel of blunt trauma or reimplantation of teeth is resorption of the root.

Dentoalveolar trauma can also involve the surrounding alveolar bone. The alveolar bone usually breaks in segments, leading to malocclusion, pain, and a segment of teeth that are misaligned with respect to their uninvolved neighbors (Fig. 60.19). These injuries usually present in conjunction with injury to the tooth itself.

| TABLE 60.3 Recommended Antibiotics for Deep Neck Infections |
|-----------------------------|----------------|----------------|
| **ANTIBIOTIC** | **DOSEAGE** | **NOTES** |
| Ampicillin sulbactam plus vancomycin | 3 g IV every 6 hours | |
| | 20 mg/kg (2 g maximum) | |
| Clindamycin | 600 mg IV every 8 hours | If allergic to penicillin |
| Meropenem plus vancomycin | 1 g IV every 8 hours | If immunocompromised |

IV, Intravenous.

**Fig. 60.17.** Ellis fracture classification. Ellis class I fractures involve the enamel only; Ellis class II fractures involve the enamel and dentin; Ellis class III fractures involve the enamel, dentin, and pulp. (From Fowler GC: Management of dental injuries. Pfenninger JL, Fowler GC, editors: Pfenninger and Fowler’s procedures for primary care, Philadelphia, 2011, Elsevier/Mosby, pp 511–515, Fig. 81.2.)
CHAPTER 60  Oral Medicine

guideline; primary dentition should never be reimplanted. Reimplanted primary teeth ankylose or fuse to the bone, potentially leading to interference with the eruption of the permanent tooth. Assessing the storage medium and timing of avulsion of a permanent tooth is important as it predicts success of reimplantation.

Physical Examination

Missing teeth should be accounted for. If a tooth appears to be missing, ask if there were teeth recovered at the scene. If no tooth is visualized, examine the socket to see if the tooth has been intrusively luxated. The surrounding soft tissue should be evaluated, because parts of teeth and even entire teeth can be embedded in a deep mucosal laceration. If no tooth is found, a chest x-ray should be obtained to exclude aspiration.

The teeth should be inspected to evaluate for fractures, tenderness, and mobility. The diagnosis of subluxation can be made by gently tapping a tooth with two tongue blades: any perceptible mobility is evidence of subluxation.

The oral mucosa and tongue should be evaluated for trauma. Small lacerations can usually be managed expectantly, but larger lacerations may require repair. Evaluate injuries for foreign bodies and to ensure injuries are not full-thickness.

Diagnostic Testing

Diagnosis of a tooth fracture or luxation is clinical, but CT of the face or an orthopantomogram (Panorex) x-ray can be ordered if CT is not available. Specialized views (eg, maxillary anterior, periapical views) are used by dental professionals but are not regularly available in the ED.

Management

Prior to any manipulation of teeth, appropriate analgesia should be administered. Nerve blocks such as supraperiosteal nerve blocks (for isolated teeth) or inferior alveolar nerve blocks (for multiple traumatized mandibular teeth) are highly effective and easy to perform.

The status of tetanus immunization should be checked, and the patient should be treated according to the standard for a non-tetanus-prone wound (10-year immunization update). All patients with dentoalveolar trauma (especially those who have splinting or

Clinical Features

Historical Features

Patients invariably will have a history of dentoalveolar trauma. Replantation of a pediatric tooth depends on whether the tooth is primary or secondary. Fig. 60.20 can be used as a general

Fig. 60.18. Luxation of teeth. A, Extrusive luxation occurs when the tooth is forced partially out of the socket in an axial direction. B, Intrusive luxation of a tooth compresses the periodontal ligament and vascular supply of the pulp. It may even crush the apical bone. C, Lateral luxation occurs when the tooth is displaced in a lingual, mesial, distal, or facial direction. Fractures of the alveolar bone frequently accompany lateral luxation injuries. (From Roberts J: Roberts and Hedges’ clinical procedures in emergency medicine, ed 6, Philadelphia, 2014, Elsevier, Fig. 64.9.)

Fig. 60.19. A, Alveolar ridge fracture involving the maxillary incisors with a segment of teeth misaligned with respect to their neighboring teeth. B, Computed tomography (CT) demonstrating an alveolar ridge fracture in the axial and coronal planes, respectively. planted is not undertaken, milk is the preferred storage medium. See Table 60.4 for the approximate length of viability of a tooth based on the solution in which it is stored.

Some texts recommend soaking the tooth in a 5% doxycycline solution for 5 minutes prior to reimplantation based on experimental data with periodontal cells, but a 2015 study demonstrated no clinical benefit and obtaining the solution and completing the soaking simply delays reimplantation. Therefore, we do not recommend this practice. The 2012 International Association of Dental Traumatology guidelines list doxycycline soaking as only a consideration.

In the awake patient not at risk for aspiration, provide analgesia (eg, supraperiosteal nerve block), rinse the permanent tooth with saline, irrigate the socket to remove debris, and reimplant the tooth into the socket. Do not remove debris from the tooth that does not come off with saline, because manual removal can damage the periodontal ligament cells. After replantation, a dental consultant can provide immobilization for the reimplanted tooth. If dental consultation is not available, use periodontal dressing material (Coe-Pak) to splint the tooth to the adjacent normal

**Tooth Avulsion**

Avulsed permanent teeth should be reimplanted at the earliest opportunity. Permanent teeth should be handled only by the crown to avoid injury to the periodontal ligament at the root. In the prehospital setting, the tooth can be reimplanted or stored in an appropriate medium. Ideally, the tooth should be stored in either a commercially-available solution, such as Hank’s balanced salt solution (eg, Save-A-Tooth, EMT Toothsaver) or milk. Oral rehydration solution can also be used as a storage medium.

A 2013 literature review of all storage solutions found that milk performed better than even saliva; therefore, if a commercially-available storage solution is not available and immediate reimplantation is not undertaken, milk is the preferred storage medium. See Table 60.4 for the approximate length of viability of a tooth based on the solution in which it is stored.

Some texts recommend soaking the tooth in a 5% doxycycline solution for 5 minutes prior to reimplantation based on experimental data with periodontal cells, but a 2015 study demonstrated no clinical benefit and obtaining the solution and completing the soaking simply delays reimplantation. Therefore, we do not recommend this practice. The 2012 International Association of Dental Traumatology guidelines list doxycycline soaking as only a consideration.

In the awake patient not at risk for aspiration, provide analgesia (eg, supraperiosteal nerve block), rinse the permanent tooth with saline, irrigate the socket to remove debris, and reimplant the tooth into the socket. Do not remove debris from the tooth that does not come off with saline, because manual removal can damage the periodontal ligament cells. After replantation, a dental consultant can provide immobilization for the reimplanted tooth. If dental consultation is not available, use periodontal dressing material (Coe-Pak) to splint the tooth to the adjacent normal
CALCITIUM HYDROXIDE APPLICATION

Calcium hydroxide is used to treat dentin fractures and aids in prevention of infection and pain relief. It is supplied in separate tubes of catalyst and base.

Mix equal portions of catalyst and base on the mixing pad that is supplied with the product. A dental spatula is an ideal tool; however, a simple cotton applicator will suffice.

Dry the tooth surface prior to application by having the patient bite down on a gauze pad. Then place a small amount of the paste onto the exposed surface. It will dry within minutes.

Fig. 60.21. Calcium hydroxide application for the treatment of fractures involving the dentin (Ellis class II) and pulp (Ellis class III). (From Roberts J: Roberts and Hedges’ clinical procedures in emergency medicine, ed 6, Philadelphia, 2014, Elsevier, Fig. 64.7.)

tears to provide a 24 to 48 hour temporary splint. A resin and catalyst paste are mixed together in equal quantities to a firm consistency and molded over the anterior and posterior aspects of the involved tooth and two or three adjacent teeth on each side (Fig. 60.22). The gingiva and enamel must be completely dry; the provider’s gloves should be wet or covered in lubricating jelly to allow for ease of handling of the paste. The positioning of the tooth does not need to be anatomically perfect, just approximate. Avoid getting the paste on the occlusal surface of the tooth. Advise the patient to have a soft diet (but avoid hot liquids that may soften the packing) and follow up with a dentist within 24 hours. Doxycycline 100 mg by mouth bid for 7 days should be prescribed in adults; in children younger than 12 years old (in whom doxycycline is contraindicated), penicillin 50 mg/kg/day divided qid (maximum 500 mg qid) for 7 days is an alternative. Patients should be further counseled on brushing gently with a soft toothbrush after each meal and utilizing chlorhexidine mouth rinses twice a day for 1 week.

Soft Tissue Injuries

Generally, lacerations to the buccal mucosa do not require repair if under 1 cm. A common rule is that if food can get stuck in the laceration, it should be considered for repair. Lacerations to the gingiva that expose the base of the teeth should be repaired; this is a complex repair, however, and consultation or referral is indicated if the clinician is not experienced with the procedure. Frenulum injuries generally are not repaired. However, frenulum injuries in neonates and infants should raise suspicion of child abuse (see Chapter 177).

Tongue lacerations usually heal well without intervention unless they are gaping, have a flap, involve the muscle, cause a bifid or grooved tongue, or if hemostasis cannot be achieved otherwise. After a lingual block or direct infiltration of anesthetic and irrigation, absorbable sutures such as 4-0 chromic, Vicryl, Dexon, or Vicryl Rapide can be used. Lacerations involving the muscular layer of the tongue should be closed with one set of deep sutures that involve both the muscle and mucosa; a two-layer repair is not necessary. Full-thickness tongue lacerations can be closed either in three layers (e.g., mucosa inferiorly, muscle, mucosa superiorly) or one side of the mucosa can be repaired followed by a set of deep sutures that closes the muscular layer and opposing mucosa.

Disposition

Patients with dentoalveolar trauma usually do not need to be admitted, unless they have other concomitant trauma, uncontrolled pain, or have severe trismus preventing oral intake. All patients should have appropriate follow-up. Discharge with appropriate analgesia, antibiotics if indicated, and dental hygiene instructions.
is thought to contribute. Tooth malocclusion was previously thought to be a common etiology, but this is rare unless there is an inciting event (eg, if symptoms began after dental work with resultant malocclusion).

**Temporomandibular Joint Disorder and Dislocation**

**Principles**

**Anatomy**

The TMJ is the articulation between the squamous portion of the temporal bone and the condyle of the mandible. It is comprised of two types of synovial joints: hinge and sliding. The hinge joint action dominates during normal mouth opening, but with wide opening, translational movement occurs and the articular disc and condyle complex slide inferiorly (Fig. 60.23). When the condyle moves anterior to the articular eminence, dislocation occurs.

**Pathophysiology**

**Temporomandibular Joint Disorder.** The cause of TMD is debated, but jaw clenching and grinding associated with stress

![Reimplantation and stabilization of an avulsed tooth.](image)
Clinical Features

Historical Features

**Temporomandibular Joint Disorder.** TMD is defined as “aching in the muscles of mastication, sometimes with occasional brief severe pain on chewing, often associated with restricted jaw movement and clicking or popping sounds.” Therefore, history should focus on elucidating whether or not the patient has those features. Patients may complain of a headache, facial pain, or even an earache. Pain is often precipitated by use of the muscles of mastication (eg, chewing) or with increased ranging of the TMJ (eg, laughing, yawning).

**Temporomandibular Joint Dislocation.** The mandibular condyles may dislocate from trauma, but more often, dislocation follows extreme opening of the mandible, such as the case with yawning. Patients may have had prolonged jaw opening, such as in the case of dental procedures. They will complain of not being able to close the mouth. Recurrent dislocations are common, and patients may present knowing they have an anterior dislocation. Verbalization of their complaint is often difficult because their mouth is stuck open.

Physical Examination

**Temporomandibular Joint Disorder.** For TMDs, the main physical signs are related to three items: joint sounds, such as crepitus or a joint click upon range of motion; limitations of joint movements with pain during assisted maximum mouth opening; and muscle and joint pain and pain just anterior to the auricular canal. None of these findings alone has sufficient testing characteristics to rule TMD in or out, however. The diagnostic criteria of TMJ is outside the scope of this text, because there are many subtypes; the criteria were most recently updated in 2014 and the included reference can be used.

**Temporomandibular Joint Dislocation.** On examination, jaw dislocations are usually readily apparent. The jaw will not be able to be closed, and a depression can be felt and seen in the preauricular area; there may be the appearance of an underbite as the mandible is anteriorly displaced. Symmetry should be evaluated, because occasionally a jaw dislocation will be unilateral. If a traumatic mechanism is suspected, a secondary survey for trauma should be initiated.

Differential Diagnoses

The diagnosis of a TMJ dislocation is straightforward. However, TMD has many presenting complaints and therefore consideration for other etiologies is warranted. Pain can be secondary to pulpitis, an odontogenic infection, headache, otitis media (as ear pain is a presenting complaint of TMD), sinusitis, and trigeminal neuralgia.

Diagnostic Testing

Radiographs are not indicated for straight-forward nontraumatic dislocation, unless the diagnosis is not certain. In cases of traumatic dislocation, a panoramic view of the mandible (Panorex)
or CT scan of the facial bones should be considered to exclude the possibility of a fracture.

Management

Temporomandibular Joint Disorder

Patients with TMD often have symptoms that fluctuate over time, and therefore initial therapy should be conservative. NSAIDs, application of heat or cooling, and consideration of bite guards if the patient has bruxism are all reasonable first-line therapies. Heat therapy is typically 15 minutes at a time, four to six times daily. Refractory cases can also benefit from diazepam (2 to 5 mg by mouth tid or qid). If the symptoms are more severe, referral to a specialist is warranted because a multidisciplinary approach is often necessary to manage symptoms; there are even studies investigating transcutaneous electrical nerve stimulation therapy, and refractory cases may benefit from surgical intervention.

Temporomandibular Joint Dislocation

Reduction of a dislocated mandible is often difficult, because masseter muscle contraction must be overcome. To relax the masseter, procedural sedation and analgesia is almost invariably necessary. Either facing the patient or from behind, the emergency clinician grasps the mandible with both hands; the thumbs rest on the ridge of the mandible intraorally, posterior to the molars, and the fingers wrap around the outside of the jaw. It is best to have the patient sitting up, with a firm surface behind the head, so that posterior and inferior pressure can be exerted without accompanying movement of the patient’s entire head. Some physicians prefer to place the thumbs on the occlusal surfaces of the teeth; in this case, the thumbs are wrapped with gauze and fortified with a piece of wooden tongue blade to protect them when reduction is accomplished, because the masseter muscles can contract with tremendous force.

Firm, progressive, downward pressure is applied on the mandible to free the condyles from the anterior aspect of the eminence; the mandible is guided caudally, then posteriorly and superiorly back into the temporal fossae (Fig. 60.24). If this maneuver is unsuccessful, both hands can be used on the affected side of the mandible. The patient is advised to avoid extreme opening of the mandible, such as occurs during laughing and yawning, to begin a soft diet for 1 week, and to apply warm compresses in the TMJ area. NSAIDs and muscle relaxants may be helpful. Patients with chronic dislocation may be helped initially with the application of a Barton bandage (elastic fabricated bandage that wraps around the top of the head and mandible).
More recently (2014) a new technique was described for a hands-free approach for reduction of acute nontraumatic TMJ dislocation using a “syringe” technique.21 With this technique, a 5- or 10-mL syringe is placed between the posterior upper and lower molars (or gums if edentulous) on the affected side. The patient then gently bites down and rolls the syringe back and forth; the syringe is a rolling fulcrum that helps the anteriorly-displaced condyle slip back into its normal position.

**Disposition**

Patients with TMD and with TMJ dislocation who have been relocated can be discharged home. Those with irreducible TMJ dislocation or those with TMJ dislocation in conjunction with a fracture should have specialty consultation and may require admission for surgical reduction and fixation.

**KEY CONCEPTS**

- Assessment of airway patency, either by CT or flexible endoscopy, is important during assessment of deep space infections of dental origin. Patients with significant airway compromise should be intubated.
- Tissue infections are treated for 10 days with simple penicillin or ampicillin/sulbactam. For penicillin-allergic patients, use metronidazole or clindamycin.
- Fractures of teeth are managed differently depending on which structures are involved—enamel, dentin, or pulp exposure.
- Avulsed permanent teeth are reimplanted as quickly as possible and are best preserved in Hank’s solution; primary teeth should not be reimplanted.

CHAPTER 60: QUESTIONS & ANSWERS

60.1. A 27-year-old previously healthy man presents with dental pain and facial swelling. Physical examination is remarkable for trismus, poor dentition with diffuse periodontal disease, and inability to manage secretions. You determine endotracheal intubation is necessary. Which of the following statements regarding the patient’s management is true?
A. An awake intubation technique is indicated.
B. Pre-induction methohexital will decrease the trismus.
C. Rapid sequence induction with rocuronium is indicated.
D. Succinylcholine will worsen the trismus.
E. Transtracheal retrograde wire intubation is indicated.

Answer: A. The trismus is “mechanical,” or muscular. Neuromuscular blockade, regardless of the choice between depolarizing or non-depolarizing agents, is not likely to help. Awake intubation, using a videolaryngoscope or flexible endoscope is indicated. Transtracheal retrograde wire intubation is rarely, if ever, indicated in modern emergency practice. Traditional “muscle relaxants” are sedatives and have no direct muscle-relaxing properties.

60.2. A 21-year-old man presents with tooth pain. He underwent a left mandibular premolar extraction 3 days ago. Examination is remarkable for a painful but nonbleeding tooth socket. The face and mandible are not swollen. Which of the following statements regarding this patient’s condition is true?
A. Analgesia is the main goal of emergency department (ED) therapy.
B. Antibiotics are indicated.
C. Dental consultation in the ED is indicated.
D. Opioids are the treatment of choice.
E. Provocation of socket bleeding is encouraged to form new clot.

Answer: A. A dry socket is an exquisitely painful post-extraction syndrome that typically occurs 3 or 4 days later. The pathophysiology is loss of the healing blood clot and localized bone infection. Treatment consists of pain control. Optionally, gentle irrigation, and packing with gauze soaked in eugenol can be performed. Opioids may be used, but this would be in addition to nonsteroidal antiinflammatory drugs (NSAIDs), which are excellent analgesics for dental pain and are preferred due to the inflammatory component.

60.3. A 2-year-old previously healthy toddler presents with an avulsed tooth after hitting his mouth on the ground after a trip and fall. Physical examination is remarkable for a non-toxic appearing child who is crying and has an open slightly oozing pocket at the maxillary central incisor. Which of the following statements regarding the patient’s management is true?
A. Set-up for conscious sedation should be arranged, because the replacement of the avulsed tooth may be painful.
B. The mother should have the patient place the tooth in the patient’s mouth.
C. The tooth should be placed in milk or Hank’s balanced salt solution.
D. The tooth should be replaced in the socket as soon as possible.
E. The tooth should not be reimplanted.

Answer: E. Management of recovered avulsed teeth depends on the age of the patient and the length of time for which the tooth has been displaced. Avulsed primary teeth in a pediatric patient 6 months old to 6 years old are not replaced in the socket. Reimplanted primary teeth ankylose or fuse to the bone, so although the dentofacial complex grows downward and forward, the reimplantation site does not. There also may be interference with the eruption of the permanent tooth. Cosmetic deformity results in either case. Thus, this patient should be referred to a pedodontist for consideration of a space maintainer or cosmetic appliance.

60.4. A 25-year-old previously healthy woman presents with recurrent pain from her temporomandibular joint disorder (TMD). The pain is described as being dull, and it worsens during the course of the day. Physical examination is remarkable for tenderness on palpation over the temporomandibular...
joint (TMJ) and some spasm noted over the masseter and internal pterygoid. Which of the following statements regarding the patient’s management is true?

A. A computed tomography (CT) scan of the face would be helpful.
B. A Panorex should be obtained.
C. Patient should be prescribed narcotic agents.
D. Treatment consists of external application of heat for 15 minutes four to six times per day, soft diet, analgesics including nonsteroidal antiinflammatory drugs (NSAIDs), and a muscle relaxant, such as diazepam (2 to 10 mg up to four times per day).
E. Ultrasound of the joint should be obtained.

Answer: D. TMJ radiographs are not helpful. Treatment consists of the external application of heat for 15 minutes four to six times per day, soft diet, analgesics including NSAIDs, and a muscle relaxant, such as diazepam (2 to 10 mg up to four times per day). Patients should be referred to a dentist specializing in TMD, such as a periodontist or a periodontal prosthodontist.

60.5. A 32-year-old previously healthy man presents with a fractured maxillary lateral incisor after a mechanical trip and fall. Physical examination is remarkable for a portion of the tooth that has an ivory-yellow appearance. You determine that he has a fractured tooth. Which of the following statements regarding the patient’s management is true?

A. A calcium hydroxide paste should be used to cover the exposed dentin.
B. A dressing can be placed for comfort.
C. An urgent pulpotomy is indicated.
D. If this were a pediatric patient or an adolescent, it would be considered less serious, because children have more dentin than adults.
E. The patient will likely need a subsequent root canal.

Answer: A. This patient has a fracture involving the dentin, which has an ivory-yellow appearance. The pulp continually lays down dentin throughout the life of the tooth. In a child, the pulp is relatively large in size, and there is less dentin; the inverse is true in the adult. Because dentin is a microtubular tissue capable of preventing bacteria to percolate into the pulp chamber, fractures involving dentin are more serious in children and adolescents. In younger patients, the management of dentin fractures involves the immediate placement of a dressing of calcium hydroxide paste over the exposed dentin. Early intervention may prevent contamination of the pulp and avoid the need for subsequent root canal. In an adult, who has a greater thickness of dentin compared with pulpal tissue, there is less need for urgent referral to a dentist. A dressing can be placed on the tooth for comfort. Referral should be made to a dentist for the next working day. Fractures involving pulp exposures are true dental emergencies.
The emergent conditions that affect the eye, its surrounding tissues, and the act of seeing itself are myriad and broad in scope and include trauma, inflammatory conditions, infections, hydrostatic issues (such as, glaucoma), vascular events, structural issues, optical derangements, and neurological developments (such as, visual field cuts, anisocoria, nystagmus, diplopia). The evaluation of a chief complaint of “eye problem” may take the clinician in any of a variety of directions. Figure 61.1 represents a general orientation to non-neurological and nontraumatic ophthalmological emergencies, insofar as they incorporate four key symptoms of pain, redness, disordered vision, and swelling.

TRAUMATIC CONDITIONS

Principles

The evaluation of a traumatic injury to the eye should be anatomically methodical, considered from superficial (eyelids, conjunctival, corneal, and anterior segment) structures to deep (including ocular, retrobulbar, and periorbital) structures, keeping in mind that deep injuries may be present with minimal superficial manifestations. Many extraocular structures are found in close proximity, and concomitant, non-ocular injury is common (traumatic facial injury is discussed in more detail in Chapter 35). A detailed examination for additional injury is therefore important.

Periorbital Contusions and Eyelid Lacerations

Clinical Features and Differential Diagnosis

Periorbital contusions and eyelid lacerations present very evidently, but it is important to determine whether additional ocular injury such as a globe perforation, an orbital septal injury (suggested by prolapsed fat), a canalicular laceration (suggested by a laterally displaced puncta) (Fig. 61.2), a levator or canthal tendon laceration, or an intraorbital foreign body is present, because all require consultation in the emergency department (ED) with an ophthalmic surgeon. An eyelid or periorbital injury should not be a distraction from less visible underlying injuries to the eye itself (see sections on deeper injuries later for clinical features).

Diagnostic Testing

The emergency clinician should undertake best attempts to thoroughly examine all ocular structures, even those hidden by swollen eyelids and periorbital tissue, and evaluate visual function. With delay, swelling can increase and limit visualization. Early examination, gentle pressure to displace fluid, or use of ice can improve ability to open the eyelids, whereupon an assessment for deeper injuries can be made. Use of eyelid retractors, such as the Desmarres, can help avoid increasing intraocular pressure (IOP). However, if there is concern for a ruptured or perforated globe (with or without a foreign body present) and the globe cannot be safely and properly examined, computed tomography (CT) imaging, with or without consultation with an ophthalmologist, is advised (see Intraocular Foreign Bodies and Globe Rupture later).

Management and Disposition

Isolated soft tissue injury to the eyelids and the surrounding area is treated with symptomatic management such as head elevation and cool compresses, as most will resolve. Patients should be instructed to seek follow-up care for any increase in pain or swelling, decreased vision, double vision, or significant flashing lights or floaters as these may be indications of retinal injury (see Posterior Segment/Ocular Injuries: Commotio Retinae, Retinal Detachment, Intraocular Foreign Body, and Perforated Globe later). If there are no additional complications, one can manage simple lid lacerations that are parallel to relaxed skin tension lines (exceptions for damage to important structures noted earlier) with primary closure with 6-0 or 7-0 nylon or Prolene interrupted sutures, removed within a week.

Conjunctival and Scleral Injuries: Subconjunctival Hemorrhage, Conjunctival Laceration, and Scleral Laceration

Clinical Features and Differential Diagnosis

Injuries to the conjunctiva include a subconjunctival hemorrhage (very common with blunt or penetrating injury) and conjunctival laceration. A subconjunctival hemorrhage develops when subconjunctival blood vessels bleed, either spontaneously or after a sudden acute venous congestion of the head, such as from a Valsalva maneuver or vigorous coughing. The hemorrhage smoothly and minimally raises the overlying conjunctiva, with no vessels visible behind the blood, and is often incidentally discovered by the patient upon looking in the mirror (Fig. 61.3). Symptoms, if any are present, may include a very mild, diffuse foreign body sensation (from the size and location of the hemorrhage), with no change in visual acuity.1 Subconjunctival hemorrhages from minor instigations (such as, coughing) are typically self-limited, but those from more direct trauma may be complicated by underlying injury. A 360-degree area of involvement associated with chemosis or pain, decreased visual acuity, or sensitivity to light, should prompt an evaluation for globe perforation. A conjunctival laceration will present with significantly more discomfort than a subconjunctival hemorrhage, and if present, should prompt an evaluation for globe perforation—and retained foreign body if indicated. A globe perforation from a related foreign body may present in an occult fashion, with only a mild-appearing conjunctival laceration or scleral “bruise,” and should be screened for if the mechanism of injury (such as, in an injury from a compressed air tool or gun, a nail or object deflected by a hammer, or a significant impact directly on the eye) suggests energy sufficient for globe penetration. A patient may also present with a scleral laceration, a laceration of the thick white envelope that provides the structural integrity of the globe, which should also prompt consideration of globe perforation.
Fig. 61.1. An overview of nontraumatic, non-neurological ophthalmological conditions, arranged by primary presentation in the emergency department (ED). Relative text size is a general representation of the incidence or relatively likelihood of that entity in relation to others. (Note: The actual incidence or likelihood of the entity in any one ED will vary with the local disease patterns and patient population being treated in the department.)

Fig. 61.2. Canalicular laceration. A, This patient experienced a laceration of the upper canaliculus. B, Canalicular laceration extending from forehead and brow. (A, From Zitelli BJ, Davis HW, editors: Atlas of pediatric physical diagnosis, ed 5, St Louis, 2002, Mosby. B, Courtesy Jeffrey Lee, MD, University of California San Diego.)
There is no evidence to support the use of artificial tears or lubricants. Patients with simple subconjunctival hemorrhage are advised regarding the gradual resolution of their hemorrhage over 10 to 14 days, with the typical colorations associated with resolving hemorrhage. No follow-up is required unless the patient develops recurrent hemorrhages or new symptoms. Although most conjunctival lacerations do not require repair, lacerations that are more than 1 cm should be evaluated by an ophthalmologist in the ED for possible repair. Although there is no evidence to support the practice, topical antibiotic prophylaxis for 3 to 5 days (usually in ointment form; Table 61.1) is common practice. A deeper scleral laceration requires emergent consultation with an ophthalmologist, and may predispose to endophthalmitis. A full-thickness scleral laceration should be treated as a globe perforation.

**Corneal Injuries: Corneal Abrasions, Foreign Bodies, and Lacerations**

**Clinical Features and Differential Diagnosis**

Traumatic corneal injuries come in three varieties: (1) abrasions, (2) foreign bodies, and (3) lacerations (which may also go into...
cornea and becomes embedded, such as seen with debris impact from a grinding tool. A corneal laceration is typically sustained from a direct lancinating injury to the surface of the eye, such as by an infant’s fingernail sweeping by the eye of its mother. All of these injuries present with more intensity than a conjunctival or isolated scleral injury, with significant foreign body sensation, pain, tearing, and a decrease in visual acuity if the abrasion, object, or laceration infringes upon the visual axis. A foreign body may actually be conjunctival and not imbedded in the cornea, presenting with more diffuse irritation, or sensation reported by the patient as “something under the eyelid,” but may cause a corneal abrasion and more intense, localized foreign body symptoms upon subsequently being moved across the surface of the eye by blinking or rubbing the eye. As with a conjunctival and scleral injury, a perforated globe should be considered in the differential diagnosis of a corneal injury, suggested by symptoms and signs (such as, chemosis, deep eye pain, decreased visual acuity, and/or photophobia) and injury mechanism.

Diagnostic Testing

With corneal abrasions and foreign bodies, topical anesthesia (see Table 61.1) can not only facilitate patient cooperation, but it help localize the extent of injury; focal pain that is completely abolished by topical anesthesia, with no signs of deeper injury present, suggests an injury confined to the superficial layers of the cornea. This does not obviate the need for a detailed examination with a slit lamp and fluorescein staining, with diagnostic goals as outlined by topical anesthesia, with no signs of deeper injury present, suggest the latter are loss of anterior chamber depth, prolapsed iris (Fig. 61.7A), an irregular or teardrop-shaped pupil (see Fig. 61.7B), blood in the anterior chamber (Fig. 61.8), and a 360-degree subconjunctival hemorrhage. Testing for a positive Seidel’s test with fluorescein, as described for conjunctival injuries earlier, can be used to confirm (but not exclude) an open globe. A critical point is that corneal perforation is a form of open globe, and once this is found, the examination ends (so as to prevent the additional extrusion of globe contents, worsening visual outcome) until the

</table>

patient can be further examined under controlled conditions by an ophthalmologist (see Intraocular Foreign Bodies and Globe Rupture later).

If the mechanism of injury involves a high-velocity projectile and no foreign body is seen on slit-lamp examination but is suspected, then an evaluation for an intraocular foreign body as outlined in Intraocular Foreign Bodies and Globe Rupture later should be initiated.

Management and Disposition

**Corneal Abrasions.** There is no evidence that treatment of corneal abrasions with topical antibiotics, as often recommended, has any beneficial effect. Furthermore, the infection rate of untreated corneal abrasions is low—at 0.7%—and prophylactic antibiotic use is not warranted. We recommend that antibiotics not be used for uncomplicated corneal abrasions (that are not deep, not imparted by a heavily contaminated object, and not in high-risk patients), especially because the indiscriminate prescribing of these agents introduces the risk of toxic and allergic medication reactions in the eye. It is reasonable, however, to empirically treat a corneal abrasion in a contact lens wearer or immunocompromised patient with an anti-pseudomonal agent such as tobramycin, ciprofloxacin, or ofloxacin, as outlined in Table 61.1 (although for a shorter course than would be prescribed for an already established infection; ie, 3 to 5 days).²

A major goal in the treatment of a corneal abrasion is managing the pain. Topical nonsteroidal antiinflammatory drugs (NSAIDs), such as ketorolac or diclofenac (see Table 61.1) are options.³ Prospective trials have revealed that topical anesthetics self-administered as needed for a short duration of time by ED patients for corneal abrasion pain results in significant pain relief without complications.⁴ Meta-analyses incorporating these trials as well as postoperative ophthalmology literature support this finding.⁵⁶ A patient with a corneal abrasion can therefore be provided a limited 24– to 48-hour course of a topical anesthetic (see Table 61.1), because the most intense pain occurs in the first 24 hours. This being said, uninformed patients using over-the-counter topical anesthetics for otherwise simple corneal injuries can develop an erosive keratopathy.⁷ Regardless of whether this association is due to masking the pain of an emerging infection or due to a direct toxic effect from a misused anesthetic, it is important to counsel patients on the correct and limited use of these agents. Eye patches are not recommended, because they can mask a worsening infection. Urgent ophthalmologic consultation is warranted with signs of active infection, such as a corneal infiltrate (whitening of the cornea) or ulceration (see Corneal Ulcers and Infiltrates later); otherwise, the patient can follow up with an ophthalmologist in 24 to 48 hours.

**Corneal Foreign Bodies.** Foreign bodies of the cornea and conjunctiva—especially those containing iron (given the propensity for worsening rust deposition over time)—should be removed in the ED if possible, using a topical anesthetic (see Table 61.1) for comfort. Corneal foreign bodies can be removed by moist cotton-tipped applicator or, if needed, by using a 25-gauge or 27-gauge needle carefully applied in a plane tangential to the surface of the cornea, under slit-lamp visualization. Non-corneal conjunctival foreign bodies can be removed by irrigation, a wet cotton-tipped applicator, or fine forceps if needed. For metallic foreign bodies, residual rust rings can be removed 24 to 48 hours later, because the rust will migrate toward the corneal surface and be more accessible. Ophthalmologic consultation is recommended for deep and large corneal foreign bodies or if the central area of the visual axis is involved. Considerations for topical antibiotic prophylaxis are the same as for corneal abrasions (see earlier).

**Corneal Lacerations.** Large but partial corneal lacerations should be evaluated by ophthalmology for potential closure in the operating room versus observation with medical therapy (topical cycloplegics and antibiotics; see Table 61.1), pressure patch, and possible tissue grafts. Smaller corneal lacerations can be evaluated and treated as corneal abrasions (with the only modification being
they should be empirically treated with topical antibiotic prophylaxis given their depth. A complication of a corneal laceration or abrasion is an infected corneal ulcer (see Corneal Ulcers and Infiltrates), which may develop days to weeks later.

**Anterior Segment Injuries: Traumatic Hyphema, Iritis, Cyclodialysis, and Lens Dislocation**

**Clinical Features and Differential Diagnosis**

Any blunt or penetrating injury of the eye may result in injury to the underlying anterior chamber, the iris, lens, and associated anterior segment structures of the eye. A traumatic hyphema (blood in the anterior chamber from ruptured vessels in the ciliary body or iris) can present with a spectrum of severity, from microhyphema (where red blood cells only visible by slit-lamp examination are suspended in the anterior chamber aqueous), to a layered hyphema (where a layer of blood may be observed grossly in the lower anterior chamber), or to a full or total hyphema (in which the entire anterior chamber is filled with blood). A microhyphema may not be visible to the naked eye but will be associated with suggestive clinical features that include peri-limbal conjunctival injection (ciliary flush), abnormal pupil size (larger, smaller, or irregular), and dilated pupils (traumatic mydriasis) (Fig. 61.9). Symptomatically, patients may experience blurry vision and photophobia (from ciliary spasms) from a simultaneous traumatic iritis (iridocyclitis). A traumatic hyphema from a blunt injury may also be associated with a cyclodialysis, a tear in which the ciliary muscle is avulsed from a scleral spur.9,10

A blunt injury to the eye can also weaken the lens zonule complex and result in a lens dislocation (Fig. 61.10A). Predisposing factors for lens dislocation include Marfan’s syndrome, homocystinuria, and high degrees of myopia. Patients may complain of monocular diplopia, distorted images, and blurred vision, and have other signs related to the trauma, such as traumatic mydriasis, iridocyclitis, and hyphema.

**Diagnostic Testing**

A diagnosis of a traumatic hyphema can often be missed without the illumination and magnification with a slit lamp. One sequela is increased IOP, and therefore the pressure should be measured (assuming there are no signs of globe rupture). An elevated IOP occurs up to 3 days after the initial injury in approximately one-fourth of patients; it is typically self-limited, but in certain instances can be high and persist and can lead to optic nerve injury and vision loss. Photophobia in the injured eye, especially if occurring on illumination of the opposite eye, strongly suggests a traumatic iritis. A cyclodialysis will be evident on slit-lamp examination as a separation of the edge of the iris away from the limbal margin.

A lens dislocation may be evident on slit-lamp examination; one may see the edge of the natural lens (which is normally not visible whether or not the patient is dilated) (see Fig. 61.10B), phacodonesis (shimmering of the lens with eye movement), and iridodonesis (shimmering of the iris with eye movements), which are evidence that the lens zonules have been compromised. A displaced crystalline lens may also be visible on ultrasound (using a large amount of gel to minimize any pressure from the ultrasound probe on the eye).11 Depending on the lens location, additional findings including increased IOP (secondary to angle closure glaucoma), corneal swelling, and intraocular inflammation may be present.

**Management and Disposition**

**Traumatic Iritis, Hyphema, and Cyclodialysis.** With isolated traumatic iritis, the primary goals of treatment are minimizing scarring, decreasing inflammation, and pain relief. This is often best achieved with a paralytic agent for the iris and ciliary body (eg, homatropine or cyclopentolate; see Table 61.1). Topical ophthalmic steroid drops (eg, prednisolone acetate; see Table 61.1) are considered in cases where significant post traumatic inflammation is present; however, caution should be applied in cases of corneal abrasions. Close follow-up with ophthalmology within 48 hours is warranted to ensure injury does not result in other ocular issues, such as glaucoma, corneal damage, and hypotony.
Both easily visible (see Fig. 61.8) and subtle traumatic hyphema deserves attention in follow-up to help minimize the likelihood of long-term complications. These complications include corneal staining and elevated IOP, which should be monitored and followed up to ensure proper resolution. In the past, recommended treatments for hyphema included strict bedrest with the head of bed elevated at least 30 degrees (presumably to allow blood to settle and filter out inferiorly) and restriction of work requiring near-vision (since accommodation may stress injured blood vessels). However, there is no evidence that strict bedrest has any effect on outcome or that head of bed position affects resorption rate in a consistent manner, so a patient with an uncomplicated hyphema can be discharged home with gentle ambulation allowed, with head of bed elevation simply to keep hyphema that is larger from clotting in the visual axis. The recommendations for pediatric patients with uncomplicated traumatic hyphema are identical; admission to hospital is not warranted, because it results in no discernable benefit.

Admission is recommended, however, for patients with hyphema of greater than 50% (in which the large volumes of blood can lead to severely high IOP and permanent corneal damage), sickle cell trait (in whom sickling of red cells in the naturally hypoxic and acidic anterior chamber prevents egress of aqueous humor and blood products), uncontrolled IOPs, and anticoagulated patients (in whom there is concern for re-bleed). Topical and oral agents to lower IOP are appropriate, but carbonic anhydrase inhibitors should be avoided in sickle cell patients. Antifibrinolytics, such as systemic or topical aminocaproic acid, may also be considered, because they have been shown to reduce the rate of recurrent bleeding even if they do not affect final visual acuity. Initiation of these treatments are best deferred to an ophthalmologist.

For patients discharged with a traumatic hyphema, next-day follow-up with an ophthalmologist is recommended to assess IOP and to evaluate for indications for urgent paracentesis of the anterior chamber or an emergent trabeculotomy, such as inability to clear the hyphema, uncontrolled IOP, or rebleeding (which occurs in 6% to 33% of patients within 2 to 5 days). Patients—particularly those with 20/200 vision or less in whom a rebleed might go unnoticed—should be followed for 3 days to identify these developments. Patients with underlying traumatic iritis may be prescribed cycloplegics (homatropine; see Table 61.1), but there is little evidence to support their use for hyphema without iritis; there is also no evidence that eye patching—postulated to prevent photosensitization of the corneal endothelium by protoporphyrin, a blood product—has any effect.

The patient with a cyclodialysis can be treated with topical cycloplegics (see Table 61.1) to relax the iris and ciliary body and be referred to an ophthalmologist for routine outpatient follow-up; small tears tend to resolve spontaneously and can be managed conservatively, whereas large ones may be permanent and—especially if causing visual issues due to hypotony—may require surgery to re-attach.

**Lens Subluxation and Dislocation.** Lens subluxations or dislocations can be vision-threatening emergencies and should be evaluated by an ophthalmologist in the ED for potential treatment, both medical and surgical.

**Posterior Segment/Ocular Injuries: Commotio Retinae, Retinal Detachment, Intraocular Foreign Body, and Perforated Globe**

**Clinical Features and Differential Diagnosis**

A more significant mechanism increases the possibility of a deeper ocular injury, and the spectrum of injury includes commotio retinae, a retinal or vitreous hemorrhage, a retinal detachment, an intraocular foreign body and a perforated globe.

Three main sequelae of a blunt injury to the retina are commotio retinae, retinal or vitreous hemorrhage, and retinal detachment or tear. Commotio retinae, also known as Berlin’s edema, can occur after ocular trauma. One study showed that it was present in approximately 6% of patients who had surgically treated orbital blowout fractures. With a retinal or vitreous hemorrhage, patients can experience vision compromise ranging widely from dark floaters to vision blackout. A retinal detachment can present with floaters and/or flashes of light (photopsia) and eventually cause a curtain-like blocking of the patient’s vision as it evolves into a retinal detachment. Because the retina has no pain receptors, patients are usually pain-free.

An important evaluation after blunt trauma to the orbit is to determine if a globe perforation (ruptured globe) or intraocular foreign body are present. Besides pain and decrease in vision, other signs as previously mentioned (loss of anterior chamber depth, irregular or tear drop-shaped pupil, blood in the anterior chamber, 360 degree subconjunctival hemorrhage, and/or prolapse of uveal tissue) should be noted. When vector forces of the trauma are not enough to blow out the orbit, the forces are directed on the globe itself. Muscle insertion sites and the limbus are the most common sites of scleral rupture because these are the thinnest areas (see Fig. 61.5). Significant collateral damage of the adjacent tissue structures such as the lens, retina, uvea, and optic nerve can also occur. The patient with a globe injury may develop sympathetic ophthalmia, a vision-threatening autoimmune response to the remaining healthy eye triggered by the exposure of the previously naïve immune system to intraocular contents from the ruptured eye.

**Diagnostic Evaluation**

In some cases of retinal injury, visual acuity testing can even be normal. Commotio retinae may appear as whitening of the retina on funduscopy. The diagnostic approach to retinal detachment is discussed in more detail in the Primary Disorders of Vision section later in this chapter. In instances of a penetrating injury to the globe or orbit, careful evaluation for a retained foreign body is important. Initially, it may not be clear if a foreign body is intraocular or just intraorbital. If the suspicion for an intraocular foreign body or ruptured globe is high but the examination cannot be performed without minimal manipulation, the examination should be deferred to one performed under anesthesia and tonometry avoided. Prior to this, a CT can be performed to provide structural integrity of the globe and orbit (and location of foreign bodies); however, because it has a sensitivity of between 56% to 75% for open globe injury, it cannot be relied upon alone, and formal surgical exploration may be needed.

**Management and Disposition**

**Retinal Injuries.** A traumatic retinal detachment, if detected and treated early before the macula is involved, carries a good prognosis. About 10% of all retinal detachments are from blunt trauma. The management of retinal detachment and vitreous hemorrhage is discussed in more detail in the Primary Disorders of Vision section later in this chapter. The decreased visual acuity from commotio retinae is self-limited and resolves in a few weeks. Evaluation by an ophthalmologist in the ED is recommended, however, because the commotio can mask a retinal tear.

**Intraocular Foreign Bodies and Globe Rupture.** For a globe perforation (open globe) with or without an intraocular foreign body, an ophthalmologist should be consulted emergently, and the examination stops until the patient can be taken to the
operating room. In anticipation of potential surgery, a protective shield should be placed (so that nothing touches the eye), tetanus vaccine administered, the patient kept nil per os (nothing by mouth) (NPO), and pain and nausea controlled. The incidence of endophthalmitis (an infection of the globe; see Infectious Conditions later) following open-globe injury ranges from 2.6% to 30%, and systemic antibiotics (cefazolin or vancomycin and a fourth-generation fluoroquinolone—due to its vitreal penetration) to cover common culprits of traumatic endophthalmitis (Bacillus species, Staphylococcus aureus, Pseudomonas species, gram-negative organisms, and anaerobes) should be administered.19 Foreign bodies, especially non-metallic foreign bodies, pose the highest risk of infection.

In general, almost all intraocular foreign bodies need to be removed. For intraorbital foreign bodies, the type and location of the material influences the necessity to remove them. Removal of inert plastic, glass, and metals may cause more damage than their permanent presence, whereas organic foreign bodies typically need to be removed because of their propensity to cause infection. Siderous oxidation of ocular tissues is a late complication of iron-containing intraocular foreign bodies and can lead to visual loss. Chalcosis, a sterile inflammatory reaction to copper-containing compounds, may occur, necessitating removal of the offending object.

It is controversial whether it is necessary to avoid the use of succinylcholine for rapid sequence intubation in open globe injury because of the very theoretical possibility of a rise in IOP from succinylcholine causing further extrusion of globe contents.20 Where time and circumstances permit, we recommend rocuronium for intubation of patients with open globe injuries, but there is no hard evidence that succinylcholine will cause harm.

### Retrobulbar and Peribulbar Injuries: Orbital Wall Fracture, Retrobulbar Hemorrhage, and Optic Nerve Injury

#### Clinical Features and Differential Diagnosis

Trauma to the eye can result in disruption to tissue around the globe and should be suspected based on the mechanism and recognition of specific clinical features. Clinical signs that could indicate an acute orbital wall fracture include ecchymoses, tissue swelling, hypesthesia of the trigeminal nerve, double vision, blurry vision, enophthalmos (posterior displacement of the eyeball within the orbit), and ptosis. In an orbital floor fracture, a medially-hinged bony “trapdoor” fragment may have transiently displaced inferiorly, allowing herniation of orbital contents into the maxillary sinus. Associated globe injuries occur in 10% to 25% of patients with orbital floor fractures. A patient can develop a vision-threatening injury without an orbital wall fracture, specifically a retrobulbar hemorrhage. The orbit is essentially a continuous cone-shaped fascial envelope with rigid bony walls on all sides (except anteriorly where the orbital septum forms an inflexible boundary), in which there is little room to accommodate an increase in volume.21 A retrobulbar hemorrhage from a ruptured infraorbital or ethmoidal artery occurring with intact orbit walls will increase intraorbital pressure and can cause an orbital compartment syndrome, resulting in ischemia to the optic nerve and retina. The triad of proptosis, ophthalmoplegia, and vision suggests this process. Blunt trauma can also cause a direct optic nerve injury, causing decreased visual acuity, if not vision loss. A rare complication of an orbital fracture or retrobulbar injury is an oculocardiac reflex from peri-orbital soft tissues that—through an afferent signal via the trigeminal nerve and efferent signal via the vagus nerve—can trigger bradycardia, junctional rhythm or even asystole, with nausea and vomiting, and is potentially fatal if unresolved.

#### Diagnostic Testing

A thorough examination paying particular attention to extracocular eye movements, assessing for an afferent pupillary defect (APD; Fig. 61.11) and checking facial sensation is imperative in the diagnostic evaluation of a possible retrobulbar or orbital injury. An orbital wall fracture is most readily diagnosed with an orbital CT scan with axial and coronal fine (minimum 1.5 mm) cuts (Fig. 61.12). Less sensitive diagnostic screening tools include plain x-ray, in which suggestive signs are a bulge extending from the orbit into the maxillary sinus (“teardrop” sign) and an air-fluid level in the maxillary sinus, and bedside ultrasound (sensitivity 56% to 92%) in which a suggestive sign is bright acoustic shadowing from subcutaneous or orbital air.

Clinical signs strongly suggesting a retrobulbar hematoma include the presence of three or more of the following: pain, decreased vision, proptosis with resistance to retropulsion, chemosis, limited extraocular motility, diplopia, diffuse subconjunctival hemorrhage, increased IOP, and an APD.21 Funduscopic may reveal edema of the optic disc or retina or retinal venous congestion. A CT scan of the orbit can provide additional evidence if clinical findings are inconclusive. However, if there is significant suspicion, treatment (see the following Management and Disposition section) should not be delayed because vision loss can be permanent.

An optic nerve injury may or may not be coincidental with a retrobulbar hematoma, and clinical findings may not necessarily differentiate whether there is compression or transection. An optic nerve injury may manifest as a decrease in visual acuity, visual field deficit, a relative APD (Marcus-Gunn pupil), or a change in optic nerve appearance. The optic disc can appear normal or swollen. CT can help determine the nature and degree of optic nerve injury.

#### Management and Disposition

**Orbital Wall Fractures.** Prophylactic antibiotics are frequently recommended by consultants for orbital wall fractures, but there is no literature evidence to support their use outside of intra-operative administration.22,23 Antibiotic prophylaxis may be warranted, however, in patients with coincident sinusitis seen on CT scan, because it increases the risk of developing orbital cellulitis.20 The patient should be instructed to avoid exerting Valsalva maneuvers, and nose blowing and should be prescribed nasal decongestants, such as pseudoephedrine 30 mg every 6 hours, so as to decrease the risk of orbital emphysema. Lastly, to improve healing and decrease swelling, ice packs to the orbit for at least 48 hours is recommended. Some ophthalmologists use steroids to reduce swelling, however, this is a case by case decision. Clinical findings that warrant urgent surgical exploration (ie, within 24 or 48 hours) include early enophthalmos greater than 2 mm; large (>2 cm²) defects of the orbital floor/metallic wall; pediatric trapdoor fractures; and when CT evidence of entrapment is associated with symptomatic diplopia, gaze restriction, or a non-resolving oculocardiac reflex.21 Outside of these indications, persistent diplopia and cosmetic concerns (such as, enophthalmos) are generally not addressed until swelling subsides after 7 to 10 days. Patients can be discharged for reevaluation by an ophthalmologist in 1 to 2 weeks. Children with orbital wall fractures are a special consideration, because they are more predisposed to “green-stick” fractures of the orbital wall and develop fibrosis and shortening of the affected muscle within a couple of days, affecting ocular function; thus, children with orbital wall fractures should be seen by an ophthalmologist in 1 to 2 days.23

**Retrobulbar Hemorrhage.** The loss of vision associated with a retrobulbar hematoma is irreversible within 60 to 100
loss. In the meantime, IOP-lowering agents (such as, intravenous [IV] carbonic anhydrase inhibitors, topical beta-blocker, alpha agonists, and in some cases 1 to 2 g of IV mannitol per kilogram) can be used. However, once ischemia and vision loss sets in, time is of the essence, and—depending upon the availability of an ophthalmologist in this time frame—a lateral canthotomy may need to be performed by the emergency clinician as a temporizing, vision-saving measure before definitive decompression (Fig. 61.13).25

Optic Nerve Injury. Once the determination of the type and degree of optic neuropathy is determined, treatment options can be considered. Surgical decompression of orbital canal fractures that impinge the nerve is not clearly beneficial, and steroids for traumatic optic neuropathy in general do not provide any additional benefit over observation.26 In both cases, an ophthalmologist should be consulted in the ED for potential therapy options.

Chemical Exposures and Glues

Clinical Features

In addition to blunt or penetrating trauma, the eye can also be injured by chemical exposures. Chemical burns can lead to devastating vision loss. Acids burns precipitate and do not penetrate as deeply into tissue (due to coagulative necrosis, in which the
precipitation of tissue proteins limits the depth of the injury). The one exception to this is hydrofluoric acid, which may rapidly pass through cell membranes and enter the anterior chamber.\(^2\) Alkaline burns are more severe because they produce liquefactive necrosis (because damaged tissues then secrete proteolytic enzymes as part of an inflammatory response), leading to cataract formation, damage to the ciliary body and trabecular meshwork, and irreversible intraocular damage in as little as 5 to 15 minutes.\(^2\) Another chemical exposure that may present in the ED is superglue to the eye. Cyanoacrylate is often used in ophthalmological surgical procedures and is relatively nontoxic to the eye. The main issues arising from superglue exposure are adhesion of eyelashes, which is difficult to reverse, and concurrent conjunctival and corneal abrasion.\(^2\)

### Differential Diagnosis

It is important to treat all unknown chemical exposures as an acidic or alkali exposure until proven otherwise. Certain substances, such as detergents and solvents, can lead to epithelial injury and anterior chamber inflammation, which then should be treated based on their particular findings (abrasion/iritis). Signs of a potent chemical exposure include periorbital edema and erythema, de-epithelialized skin, and loss of eyelashes and eyebrows, corneal and conjunctival epithelial defects, chemosis, corneal cloudiness, sterile ulceration, edema, and perforation. Elevated IOP may result from damage and/or inflammation of the trabecular meshwork. Although a determination of the pH of the solution involved is the most important consideration, other factors in the exposure (such as, temperature, amount, impact force, concentration, osmolarity, and redox potential) can greatly influence the pathophysiology of chemical tissue damage.\(^2\)

Accessing the material safety data sheet (MSDS) of the agent involved or consulting with a Poison Center can greatly facilitate identification of the offending agent and guide the appropriate treatment. If the exposure occurred as a result of explosion, penetrating globe injury may also be present.

### Diagnostic Testing

Treatment of a chemical exposure should begin as soon as possible with copious irrigation, even prior to arrival to the ED. The initial basic ophthalmic examination should pay attention to an inspection of the fornices, to ensure that there is no remaining chemical...
Management and Disposition

For acid or alkaline burns, irrigation of the eye should be performed immediately. The longer irrigation is delayed, more irrigation volume will likely be required because the chemical can deposit within the tissue. It may take up to 20 L or more to change the pH to a physiologic level (a goal pH of 7 to 7.5). Based on animal studies, traditional isotonic saline irrigation solutions may be relatively ineffective at neutralizing a significant exposure to an alkaline agent (such as, sodium hydroxide) within the 20 minute time frame required to reduce injury and that buffered irrigation products specially designed for the task are significantly more effective. This being said, initiation of irrigation with whatever solution is being obtained. Surprisingly, tap water is more effective than saline and is therefore recommended for acid or alkaline burns. It is also better tolerated than saline and is therefore recommended in situations in which a buffered product is not available. Use of topical anesthesia (see Table 61.1) and assistive devices, such as a Morgan lens and an eyelid retractor, can aid in delivering the irrigation more effectively. Emergent ophthalmological consultation is warranted in significant acid burns, and all alkaline burns, especially those in which irrigation to a pH of 7 required copious irrigation. In chemical exposures deemed to have a low risk of significant injury (an assessment of facilitated by contact with a local poison center) without signs of immediate ocular injury (such as, corneal burns), the patient can be treated and referred for follow-up with an ophthalmologist in 24 to 48 hours.

For more significant chemical injuries, cycloplegics, antibiotics (ointments are usually preferred because they also provide comfort), and occasionally steroid drops are indicated (see Table 61.1 for agents and dosing). After the acute treatment has been completed, obtaining additional history (such as, the nature of the substance) can be useful in determining prognosis; substances with pH ranging from 2 to 12 with limited contact time tend to have a better prognosis. However, at the time of presentation, the severity and complications of the injury may not be completely assessed because the full extent of the injury has not yet occurred. These complications can include permanent corneal injury (Fig. 61.14), glaucoma, palpebral and conjunctival adhesions, cataracts, and retinal injury.

In the case of superglue, cyanoacrylate does not bond well to wet surfaces, and an exposure into the eye typically results in a forceful blink and extrusion of the glue onto the dry surfaces of the lid margins. Gentle traction will often separate glued eyelashes; if not, trimming with Westcott scissors can help. Examination by slit lamp can help determine which lashes can be more readily separated. Time will help loosen the adhesions and allow for removal of the glue. If there is eyelid malposition, cutting the lashes can often allow for normalization of the eyelid position. Attempts to dissolve the glue with other substances (especially acetone) should be avoided, because they may cause ocular damage. Ophthalmology consultation in the ED is recommended for cases in which the above measures fail to separate the lids to enable an examination, if there is residual eyelid mal-positioning, or if there is a suspected corneal abrasion from the hardened glue. If separating eyelids reveals no evidence of subsequent lid malpositioning and no sign of conjunctival involvement or injury, the patient can be referred to an ophthalmologist for follow-up as an outpatient in the next day.

INFLAMMATORY CONDITIONS

Principles

Inflammatory conditions of the eye tend to present as a “red eye,” which is a general term that encompasses a variety possible etiologies in the conjunctiva, cornea, globe and surrounding orbit. The clinical approach to the red eye in general (which includes not just inflammatory processes but also infectious processes) is described in detail in Chapter 19.

The Conjunctiva and Cornea: Keratitis, Pterygium and Pinguecula

Clinical Features and Differential Diagnosis

Conjunctival and corneal inflammatory conditions present in a somewhat stereotyped fashion and include allergic conjunctivitis, superficial punctate keratitis, ultraviolet (UV) keratitis (radiation keratitis), and pterygium and pinguecula. Allergic conjunctivitis, although technically an inflammatory process, is similar enough in presentation to infectious conjunctivitides that it is considered together with the infectious processes outlined later this chapter.
Superficial punctate keratitis presents with pain or foreign body sensation, photophobia, and redness due to poor lubrication of the corneal surface from any one of several etiologies, including dry eyes, drug toxicity, and contact lens overuse. UV keratitis is a specific form of keratitis that presents when prolonged exposure to UV light (from a source such as a tanning booth, reflection from snow or water, or a welder’s arc) causes a direct injury to the corneal epithelium, at times severe enough to cause ulceration. There is a latency of 6 to 10 hours before symptoms arise, at which point patients have a significant degree of pain and discomfort, photophobia, and mild conjunctival injection.

Another set of conjunctival inflammatory conditions, somewhat similar in appearance to one another, are pterygium and pinguecula. A pterygium is a chronic fibrovascular growth of conjunctiva triggered by chronic exposure to UV light that grows temporally from the nasal side of the eye (or vice versa), eventually covering the cornea. A pterygium can get acutely inflamed, whereupon patients experience foreign body sensation, dry eyes, and redness, but they should not have loss of vision unless the process has started to infringe upon the visual axis (a very gradual and chronic process). A pinguecula is of similar pathophysiology to a pterygium, resulting in similar symptoms, except that it stops at the limbus and does not enter the cornea or visual axis.

Clinical Features and Differential Diagnosis

Superficial punctate keratitis and UV keratitis, multiple punctate epithelial erosions are seen upon fluorescein staining. A patient with a pterygium or pinguecula will have a visible, opaque conjunctival overgrowth on the conjunctiva of one or both eyes, typically triangular or pie-shaped, with the apex of the triangle pointing towards the pupil.

Diagnostic Evaluation

Examination with a slit lamp is an integral part of the diagnostic evaluation of conjunctival and corneal inflammatory conditions. With superficial punctate keratitis and UV keratitis, multiple punctate epithelial erosions are seen upon fluorescein staining. A patient with a pterygium or pinguecula will have a visible, opaque conjunctival overgrowth on the conjunctiva of one or both eyes, typically triangular or pie-shaped, with the apex of the triangle pointing towards the pupil.

Management and Disposition

Superficial Punctate Keratitis and Radiation Keratitis. Determination of etiology of the keratitis is important for definitive treatment. In general, however, care is supportive. The treatment considerations for superficial punctate keratitis and UV keratitis are the same as with conical abrasion (because both entail an injury to the corneal epithelium and superficial cornea, see Corneal Abrasions) and include limited use of topical anesthetics and topical antibiotics administered for 3 to 5 days only if infection is a concern (see Table 61.1). UV keratitis will typically resolve in about 24 hours or so, and given the nature of the injury, patients should be instructed to avoid damaging UV rays. Ophthalmologic follow-up in 24 hours is recommended if symptoms have not resolved.

Pterygium and Pinguecula. Treatment of pterygium and pinguecula is similar, and it includes UV protection, lubrication, and treatment of acute inflammation with topical NSAIDs (see Table 61.1). The inflammation of a pterygium or pinguecula is usually self-limited, and encroachment into the visual axis from a pterygium is typically very gradual; non-emergent referral to an ophthalmologist is recommended for surgical treatment of severe cases, and for evaluation of the rare coexistence of an ocular surface squamous neoplasia.

The Globe: Uveitis, Scleritis, and Episcleritis

Clinical Features and Differential Diagnosis

The globe itself can on rare occasion be afflicted by a variety of autoimmune conditions, typically involving the uvea as an autoimmune uveitis, or the sclera, as a scleritis. Three noninfectious, inflammatory considerations causing a painful red globe are uveitis, scleritis, and episcleritis.

Uveitis is an autoimmune inflammation of the uvea, the part of the middle layer of eye that includes the highly vascularized and pigmented iris, ciliary body, and choroid. The iris and ciliary body are most commonly involved, a condition called iritis or anterior uveitis, but uveitis may rarely involve the intermediate and posterior chambers as a rare panuveitis. No cause is identified in 60% to 80% of people, although uveitis is one of the most frequent extra-articular features in seronegative arthritides (including ankylosing spondylitis, psoriatic arthropathy, arthritis from inflammatory bowel disease [ie, Crohn’s], and reactive arthritis [ie, Reiter’s syndrome]). The typical patient with an acute anterior uveitis will present with a very painful red eye, often with photophobia, and occasionally with decreased visual acuity.

Scleritis is a similar autoimmune inflammatory process, but involving the sclera (the tough connective tissue layer that begins at the limbus and surrounds the eye) instead of the uvea. It is divided into anterior scleritis and the less frequent posterior scleritis (inflammation of the sclera posterior to the insertion of the rectus muscles). Scleritis can also be infectious, treated much in the same way an endophthalmitis would be (see The Globe: Endophthalmitis).

Episcleritis, which can be confused with scleritis, is caused by inflammation in the episcleral layer of the eye rather than the deeper scleral layer. Episcleritis, unlike scleritis, is not vision-threatening and is not associated with as much discomfort.

Diagnostic Evaluation

On slit-lamp examination, uveitis will typically reveal conjunctival injection, ciliary flush in the peri-limbal area, and cells and flare in the anterior chamber. Episcleritis can be distinguished from scleritis in that it is associated with more peri-limbal injection and has a redness that described as salmon pink as opposed to the deeper purple hue seen in scleritis; instillation of 10% phenylephrine drops will constrict and blanch injected superficial episcleral vessels in episcleritis but will not do so to the injected deeper vessels involved in scleritis. Scleritis is often more severe than episcleritis and has a much higher association with systemic diseases, such as Wegener granulomatosis, rheumatoid arthritis, and connective tissue disease (an evaluation that can be deferred to outpatient follow-up).

Management and Disposition

Treatment of both uveitis and scleritis typically involves topical corticosteroid drops (and cycloplegics for symptoms of iridospasm; see Table 61.1), with a transition to systemic corticosteroids and immunosuppressants if these treatments fail. NSAIDs are helpful for scleritis, although systemic steroids may be more useful in severe cases. Decisions about treatment are typically made in concert with an ophthalmologist, and patients should be referred to an ophthalmologist for close follow-up in the next day or so; scleritis has a higher association with ocular complications, including keratitis, increased IOP, and vision loss.

The Orbit: Orbital Pseudotumor, Orbital Apex Syndrome, and Thyroid Orbitopathy

Clinical Features, Differential Diagnosis, and Diagnostic Evaluation

The orbit may be affected by typically idiopathic, noninfectious inflammatory processes that lead to diffuse eye pain, redness,
swelling, and potentially disordered vision. Considerations include orbital inflammatory pseudotumor and orbital apex syndrome (which are unilateral), as well as thyroid myopathy (which is usually bilateral).

Orbital inflammatory pseudotumor (also known as idiopathic orbital inflammation syndrome, orbital pseudotumor, or orbital inflammatory syndrome) presents as an acute to subacute tumor-like inflammation consisting of a pleomorphic cellular response and a fibrovascular tissue reaction, and it is associated with various rheumatologic disorders, including Wegener’s granulomatosis, giant cell arteritis, systemic lupus erythematosus, dermatomyositis, and rheumatoid arthritis.37 In orbital apex syndrome, the apex of the orbit (through which the cavernous sinus drains the eye and orbit, and cranial nerves [CNs] III, IV, and VI travel) may be selectively affected by a cavernous sinus mass or vasculitis. Etiologies include infection, carotid-cavernous fistula, inflammatory vasculitides (such as, giant cell arteritis), Tolosa-Hunt syndrome (a rare idiopathic vasculitis), or tumor or infiltration (eg, sarcoidosis). Both orbital inflammatory pseudotumor and orbital apex syndrome may result in proptosis, chemosis, and/or conjunctival injection; and with orbital apex syndrome, there may be palsies of CNs III, IV, and VI (see Chapter 18).

Inflammatory thyroid orbitopathy from Grave’s disease is the most common cause of ocular myopathy in older adults, and it presents with oculomotor muscle swelling and restriction that may be bilateral in 85% of cases. It classically affects the inferior and medial recti muscles first, leading to restriction of elevation and abduction of the eye with orbital muscle dysfunction and misalignment of the visual axes.38 The examination may reveal stigmata of the underlying disease process, such as lid lag or periorbital swelling or proptosis, as well as diffuse conjunctival edema, and vascular injection near the insertions of the rectus muscles.

The diagnostic evaluation of a suspected orbital inflammatory process primarily involves imaging of the orbit. Options include a magnetic resonance imaging (MRI) scan of the orbits with gadolinium, which can allow an assessment for enlargement or enhancement in extraocular muscles and orbital structures, or—as a likely more readily available second-line option—a contrast-enhanced orbital CT (with fine cuts through the orbit).39

Management and Disposition

The mainstay of therapy (assuming infection is excluded) for orbital pseudotumor and orbital apex syndrome is systemic corticosteroid therapy, although there is increasing use of antitumor necrotic agents, cytotoxic agents, and other immunosuppressive agents.37 Treatment choices will typically be made in concert with an ophthalmologist. For thyroid orbitopathy, the treatment of the underlying Grave’s disease will address the ophthalmological issues but may involve immunosuppressive medications, radiation, or surgery.

INFECTION CONDITIONS

Principles

A critical clinical distinction that comes into play in a patient with a red, irritated, or painful eye is whether or not there is an infectious process in play. This is based on clinical features, keeping in mind that the globe of eye and the encompassing tissues of the orbit represent a pristinely organized and functional arrangement of tissue planes and glandular structures, and that any disruption to these structures, whether from minor trauma, prior surgery, or inflammation, can predispose to an infectious process.

The Conjunctiva: Allergic, Viral and Bacterial Conjunctivitis, and Ophthalmia Neonatorum

Clinical Features, Differential Diagnosis, and Diagnostic Testing

Symptoms of conjunctivitis—which may be allergic, toxic, or infectious—include redness, discharge, foreign body sensation, photophobia, and blurry vision.

The most common form of conjunctivitis is thought to be allergic conjunctivitis. This is not infectious per se, but it is considered in the differential diagnosis here because it is sometimes a challenge to distinguish from a viral conjunctivitis. Allergic conjunctivitis is a type 1 histaminergic hypersensitivity reaction with red itchy eyes, clear discharge, and is classically bilateral, associated with pollen and dust. In more severe cases, moderate to severe injection with glassy chemosis is observed. A toxic conjunctivitis (from topical ocular medications) may appear similar to allergic conjunctivitis; a contact dermatitis (from a trigger like eye makeup) should be suspected if there is an associated lichenified, eczematous periorbital dermatitis and edema.

Of the infectious etiologies, viral causes are most common. Viral conjunctivitis is classically preceded by a viral infection with upper respiratory symptoms, with sequential involvement of both eyes, but many viral conjunctivitis episodes have no preceding upper respiratory infection (URI) syndrome. It is most commonly by adenovirus, easily spread by contact with fomites. The conjunctival discharge with viral infections tends to be more watery and less purulent than that in bacterial conjunctivitis, with signs such as preauricular lymphadenopathy and follicular changes of the conjunctiva (Fig. 61.15). Viral conjunctivitis, and keratoconjunctivitis, however, can present with impressive purulence, including having the eyelids stuck shut when awakening from sleep. Such findings do not distinguish bacterial from viral causes. Viral infections typically last 1 to 3 weeks. Epidemic keratoconjunctivitis is a highly contagious and more virulent viral conjunctivitis often presenting in epidemics, with which the patient may also complain of foreign body sensation and have a mild keratitis.

Bacterial conjunctivitis is significantly less common than viral. The organisms involved include Staphylococcus organisms, as well as Moraxella catarrhalis, Streptococcus pneumoniae, Haemophilus influenzae and rarely Neisseria gonorrhoeae, with an increased prevalence of methicillin-resistant Staphylococcus aureus (MRSA) conjunctivitis over the last decade.40 Conjunctivitis from gonorrhea classically presents with copious purulent discharge (Fig. 61.16) and carries a high risk for corneal involvement and
subsequent corneal perforation. A gram stain and culture (or a polymerase chain reaction [PCR] test as done for genital samples) can aid in the diagnosis.

Distinguishing a viral from a bacterial conjunctivitis can sometimes be a challenge in the ED. A systematic review found that redness of the conjunctival membrane that is intense enough to obscure the tarsal vessels (likelihood ratio [LR], 4.6; 95% confidence interval [CI], 1.2 to 17.1), physician-observed purulent discharge (LR, 3.9; 95% CI, 1.7 to 9.1), and matting of both eyes (LR, 0.3; 95% CI, 0.1 to 0.8) decrease the probability of a bacterial cause, whereas inability to discern that the patient’s eye is red from 20 feet away (LR, 0.2; 95% CI, 0 to 0.8) and absence of morning matting of either eye (LR, 0.3; 95% CI, 0.1 to 0.8) increase the probability of a bacterial cause.

What appears to be an infection of the conjunctiva may actually represent an infection of the cornea, and therefore a slit-lamp examination is important; if signs of corneal involvement are present, a keratitis is in play (see Diagnostic Evaluation in The Conjunctiva and Cornea: Keratitis). Epidemic keratoconjunctivitis may have some mild punctate keratitis on fluorescein staining.

A consideration specific to neonates is ophthalmia neonatorum (see Table 61.1). Treatment of a bacterial conjunctivitis suspected to involve N. gonorrhoeae consists of ceftriaxone 1 g intramuscularly once, and saline irrigation of the affected eye(s), with concomitant empirical treatment for Chlamydia trachomatis infection (either 1 mg of azithromycin orally once, or doxycycline 100 mg orally bid for 7 days).

**Bacterial Conjunctivitis.** Although bacterial conjunctivitis is typically self-limited, most resolving in 1 to 2 weeks without treatment, topical antibiotics shorten the time to resolution. Ointment is preferred giving the smoothing effect on the eye and ease of instillation (patients know if ointment was applied or not and have to do it less frequently). The prescribed antibiotics (see Table 61.1 for options) should cover the organisms mentioned previously and be taken for at least 1 week; those with the highest level of evidence for the treatment of bacterial conjunctivitis are tobramycin, ciprofloxacin, moxifloxacin, ofloxacin, azithromycin, and trimethoprim/polymyxin B. Gentamicin and neomycin should be avoided due to toxicity. Contact lens wearers should have coverage for *Pseudomonas* (see Table 61.1).

**Ophthalmia Neonatorum.** Hospitalization of neonates with blood and cerebrospinal fluid examination may be indicated for ophthalmia neonatorum. *N. gonorrhoeae* conjunctivitis in a neonate is typically treated with single dose of ceftriaxone 25 to 50 mg/kg up to a total dose of 125 mg intramuscularly, topical erythromycin or polymyxin B–bacitracin ointment, and saline washes of the affected eye. Potential ocular chlamydial infection is often simultaneously treated with topical erythromycin ointment and oral erythromycin syrup 50 mg/kg/day divided into four doses per day for 14 days. HSV should be treated with acyclovir IV 45 mg/kg/day plus vidarabine 3% ointment five times per day for 14 to 21 days. Evaluation for systemic involvement is indicated and ophthalmology consultation in the ED is warranted.

**The Cornea: Corneal Ulcers, Herpes Simplex Keratitis, and Herpes Zoster Keratitis**

**Clinical Features and Differential Diagnosis**

What appears to be conjunctivitis may actually represent an infection of the cornea. A *corneal ulcer* (Fig. 61.17) is an infectious and/
or inflammatory erosion, “ulcerative keratitis,” of both the outer epithelial cell layer and the underlying stromal layer (which is the bulk of the cornea). Corneal ulcers present with pain and redness of the eye, tearing, sensitivity to light, and blurred, hazy, or otherwise decreased vision. There can also be discharge or a foreign body sensation. A corneal abrasion can become an ulcer if secondarily infected, which in turn lead to corneal perforation if severe and untreated. Although corneal ulcers are due to infection, most of the resulting corneal injury is due to the secondary inflammation. The most common bacterial pathogens are Staphylococcus, Streptococcus, Mycobacterium, and Pseudomonas, which is associated with contact lens wear. Fungal pathogens are typically seen in users of corticosteroid drops, and in agricultural workers and others who may have contamination of the eye with vegetable matter or soil.

The cornea can also be infected by viruses. Herpes simplex keratitis, one of the most common causes of viral keratitis, can produce recurrent corneal ulcers similar to recurrent herpes labialis or herpes genitalis. Herpes simplex may be either primary or reactivation of preexisting disease. Symptoms are similar to corneal ulcers. Herpes zoster keratitis can occur in the setting of herpes zoster ophthalmicus. Herpes zoster is re-activated along the ophthalmic division of the trigeminal nerve, and eye involvement is possible. Patients will typically present with a dermatomal rash over the forehead and upper eyelid and sometimes along the nose (branch of the nasociliary nerve—called Hutchinson’s sign), or even have a local Horner’s syndrome.

**Diagnostic Testing**

The foundation of the diagnostic evaluation of corneal lesions is a careful examination and biomicroscopy with the slit lamp and fluorescein staining to evaluate corneal epithelial surface disruptions. On slit-lamp examination, a corneal ulcer may appear to have more “heaped up” edges (seen with tangential lighting) than those seen with a corneal abrasion; this finding, combined with stromal edema or infiltration (whitening of the underlying or surrounding cornea), helps red-flag the process as an ulcer instead of an uncomplicated abrasion.

A corneal ulcer from herpes simplex keratitis may present with classic “dendritic” lesions on slit-lamp examination (Fig. 61.18), or with an amoeba-shaped ulceration, or have nonspecific findings such as punctate epithelial erosions, stromal whitening, and thinning of the cornea, possibly with classic herpetic vesicles located on the lids or conjunctiva. Herpes zoster keratitis may appear somewhat similar but will have signs of a dermatomal vesicular rash, and it is frequently associated with iritis, uveitis, and choroiditis. Viral cultures of tissue can help direct therapy.

**Management and Disposition**

**Corneal Ulcers and Infiltrates.** Topical anti-microbial therapy for corneal ulcers and infiltrates is appropriate, although in some severe cases, systemic antibiotics may be warranted. The fluoroquinolones (see Table 61.1) have particularly good ocular penetration; doxycycline and other tetracyclines have good anti-collagenase properties that help preserve corneal integrity. Steroids may be used to decrease inflammation but must be used with caution, because they may exacerbate the clinical situation (and if a herpetic process is suspected, steroids may have to be avoided, or antivirals concurrently used). Ophthalmology consultation in the ED is important for management of corneal ulcers, because they can rapidly progress.

**Herpes Simplex Keratitis.** Herpes simplex keratitis is the most common cause for corneal transplants in the United States. Emergent ophthalmologic consultation is advised, because the severity of disease will dictate treatment. Herpes simplex keratitis is treated with topical antiviral agents, such as topical acyclovir trifluridine 1% nine times a day for 14 days. Topical prophylactic antibiotics, such erythromycin ointment, and a cycloplegic agent if there are symptoms of iritis can be considered (see Table 61.1). Topical steroids should be avoided because they worsen infection. Systemic therapy should be considered (acyclovir 400 mg five times daily or valacyclovir 500 mg three times daily for 7 to 10 days) if topical treatment is not available or if the process is severe; admission will typically not be needed, but close follow-up with an ophthalmologist within 1 to 3 days is important.

**Herpes Zoster Keratitis.** Herpes zoster ophthalmicus accounts for approximately 10% to 20% of all zoster cases and necessitates emergent ophthalmologic consultation. If not treated and recognized immediately, herpes zoster ophthalmicus may result in permanent vision loss. Systemic therapy is the standard of care (unlike HSV, topical antivirals have little effect). If retinal involvement occurs or the patient is immunocompromised, inpatient treatment is recommended. Higher dose antiviral agents (acyclovir 800 mg five times daily, valacyclovir 1000 mg three times daily, or foscarnet 500 mg three times daily, all for 7 to 10 days19) are used, and occasionally topical steroid agents and systemic antibiotics may be added. Topical antibiotics are used to prevent bacterial superinfection of skin and lid lesions.
Early treatment with antiviral therapy within 72 hours of the onset of the rash has been shown to reduce acute pain and ocular complications. Additional consideration for therapy includes pain management and aggressive lubrication to maintain a healthy ocular surface.

**The Eyelids and Periorbital Area: Hordeolum, Chalazion, Dacryocystitis, Blepharitis, and Cellulitis**

**Clinical Features and Differential Diagnosis**

The tissues of the eyelids and periorbital area are susceptible to any of a number of types of infections, which include those related to glandular or ductal structures, such as a hordeolum, chalazion, or dacryocystitis, or more diffuse involvement of tissue, such as blepharitis or periorbital cellulitis. Hordeola and chalazia, also known as *styes of the eyelid*, are inflamed oil glands of the eye. A *hordeolum* is caused by acute inflammation of a gland of Zeis or hair follicle. It is typically painfully tender, erythematous, associated with swelling, and can be infected. On the other hand, a *chalazion* is a chronic sterile, granulomatous inflammation of a meibomian gland (and may evolve from a hordeolum), which results in localized swelling that is usually not acutely painful (Fig. 61.19).

Dacryocystitis is an infection of the lacrimal sac, usually resulting from a nasolacrimal duct obstruction. It is more common in females. Symptoms and signs include pain, tenderness, swelling, and erythema over the lacrimal sac medial to the eye (Fig. 61.20). Pressure over the sac may express purulent material from the puncta. The lacrimal gland itself can also become infected, appearing as a focal area of periorbital erythema, swelling and tenderness lateral to and above the upper eyelid.

Patients with blepharitis typically describe itching and burning of the eyelids with associated tearing and crusting of the eyelids. The eyelids become diffusely inflamed and thickened, with erythematous margins, and telangiectasias surrounding the eyelid margin. Blepharitis can be distinguished from a pre-septal cellulitis in that it is isolated to just the eyelid margin. Blepharitis has an association with atopic dermatitis, rosacea, and eczema.

Any one of the aforementioned focal infections, but especially dacryocystitis and blepharitis, may be complicated by a more diffuse, associated cellulitis. Cellulitis frequently presents, however, as an individual entity, and it has to be carefully distinguished as either pre-septal (also called *periorbital*) or post-septal (also called *orbital*). Pre-septal and post-septal are the most useful terms because (1) they incorporate the most impactful clinical distinction in the ED and (2) remove any chance of confusion as to what is being referred to in communications with consultants. Pre-septal cellulitis is limited to the tissue anterior to the orbital septum, whereas a post-septal cellulitis implies spread of the infection beyond the septum, which is concerning because it can lead to involvement of valuable orbital structures. Pre-septal cellulitis will present with lid erythema, warmth, tenderness, swelling, and even a low-grade fever. Post-septal cellulitis will present with the same but may also have more alarming symptoms including proptosis, ophthalmoplegia, pain with eye movement, chemosis, and systemic signs of infection. In very severe cases, visual loss can occur. In children, pre-septal cellulitis is often more difficult to differentiate from a post-septal cellulitis because of an incomplete orbital septum.

**Diagnostic Testing**

For hordeolum, chalazion, dacryocystitis, blepharitis, and a cellulitis that is clearly pre-septal, the diagnosis is established on the clinical examination alone, and no additional diagnostics are needed. CT imaging is, however, indicated in cases concerning for an orbital abscess or in which localization of an infection (pre-septal or post-septal) is difficult. In such cases, a complete blood count (CBC) may also be helpful. The primary diagnostic decision for the ED patient with a cellulitis around the eye is deciding who needs further evaluation with a CT scan. Symptoms and signs of proptosis, ophthalmoplegia, pain with eye movement, and chemosis easily suggest the possibility that a cellulitis is post-septal,
but upward of 50% of confirmed cases may not have these symptoms. In these “no orbital symptom” cases, a peripheral absolute neutrophil count (ANC) of >10,000 cells/µL, moderate-to-severe periorbital edema (extending beyond the eyelid margins), absence of conjunctivitis as the presenting symptom, older than 3 years old, and recent antibiotic use have been shown to be predictors of an orbital abscess—specifically in the pediatric population. In addition, a sudden onset is more typical of a post-septal orbital cellulitis. The absence or presence of a fever has little discriminatory utility. Cultures obtained from swabs of the eyes are discouraged due to the risk of misleading results from inoculation with commensal organisms, and blood cultures have little diagnostic utility.

Management and Disposition

Hordeolum and Chalazion. Often, hordeola and chalazia are self-limited and can resolve on their own when the glands become unobstructed. Conservative treatment to normalize flow of the obstructed oil glands is the primary goal. This includes warm compresses for 10 to 15 minutes, 3 to 5 times a day. Treatment of an underlying blepharitis may be indicated. Referral to an ophthalmologist is recommended for incision and drainage or additional management and evaluation in nonresponsive cases. Progression to an infected oil gland may indicate need for antibiotics, depending whether the process takes the form of a blepharitis or a cellulitis (see treatment of each in the following sections).

Dacryocystitis. The most common causative organisms in dacryocystitis are S. aureus, S. pneumoniae, H. influenzae, Serratia marcescens, and Pseudomonas aeruginosa, with an emerging prevlance of MRSA. Treatment consists of massage, warm compresses, and systemic antibiotics selected so as to include coverage of MRSA. An attempt should be made to obtain a culture by applying gentle pressure to the nasal lacrimal duct and expressing fluid. In infants, acute dacryocystitis represents a medical emergency, because it can lead to complications including post-septal orbital cellulitis. Admission is warranted for severe cases. Occasionally, drainage of the sac is required; however, this can lead to fistula formation. Dacryocystorhinostomy is the definitive treatment, but the optimal time for surgery is when the infection is controlled. Discharged patients should follow-up with an ophthalmologist in 24 to 48 hours.

Blepharitis. The initial treatment of blepharitis is conservative, designed to remove residual oils and scurf, and entails warm massage with a moist washcloth about for 10 to 15 minutes, three to five times a day, and cleaning the lid margins twice a day with a cotton swab soaked in mild baby shampoo. Because blepharitis arises as a result of an inflammatory process, there is potential for bacterial overgrowth and superinfection (Staphylococcus epidermidis primarily, but also Propionibacterium acnes, and corynebacteria), and—if there is a concern for infection—topical azithromycin, erythromycin, or levofloxacin (see Table 61.1) can be considered. Uncomplicated cases can be discharged to follow-up with an ophthalmologist within a week or so, or within 1 to 3 days if there is concern for infection.

Periorbital Cellulitis. If pre-septal cellulitis with no other underlying medical conditions is diagnosed with certainty, the patient can be discharged on an oral antibiotics directed toward the most common organisms, Streptococcus and Staphylococcus, keeping in mind that orbital cellulitis tends to be polymicrobial. Although many practitioners empirically cover for MRSA, this organism is actually very rare when it comes to orbital cellulitis (at least in published series involving primarily children). An option is a beta-lactam antibiotic, such as oral amoxicillin-

clavulanate, 875 mg two times daily for 10 to 14 days for adults (or 20 to 40 mg/kg divided into three doses for 10 to 14 days for children). Close follow-up, with a re-examination within a day at a primary care provider’s office or with an ophthalmologist is important to assure response to treatment.

In more severe cases of post-septal cellulitis, hospitalization with IV antibiotics is indicated to avoid complications, such as subperiosteal abscess, orbital abscess, meningitis, osteomyelitis, and cavernous sinus thrombosis. In children, the difficulty in localizing the spread of the infection dictates more aggressive management of any periorbital infection. An IV second- or third-generation cephalosporin, such as cefuroxime or ceftriaxone, is recommended. Other IV antibiotic options include ampicillin/sulbactam (Unasyn), or a combination of a first-generation cephalosporin with metronidazole.

The Globe: Endophthalmitis

Clinical Features, Differential Diagnosis, and Diagnostic Testing

Endophthalmitis is an infection involving the globe itself. Pain and decreased vision are the primary symptoms. Examination findings include decreased visual acuity, chemosis, and hyperemia of the conjunctiva, intraocular inflammation (evidenced by hypopyon) (Fig. 61.21). The most common etiology of endophthalmitis is recent intraocular surgery. Other etiologies include previous perforated eye and endogenous infection. Early diagnosis and management is imperative for improved prognosis. The diagnosis is primarily clinical, and will typically have to be done in consultation with an ophthalmologist, because endophthalmitis can be difficult to distinguish from a uveitis, and the two have vastly different treatments and acuity. An ultrasound of the eye (done in much the same way as to evaluate for retinal detachment) can be used to augment the evaluation; and with endophthalmitis, it may reveal numerous stands and membranes in a vitreous that would otherwise be uniformly hypoechoic.

Management and Disposition

Endophthalmitis is a medical emergency that must be promptly treated. Systemic antibiotics are not effective, and therefore—although IV antibiotics can be considered (their effect is unknown)—intravitreal antibiotics must always be given. The evaluation and treatment should be done in consultation with an ophthalmologist who can administer the intravitreal antibiotics at the bedside and perform a vitrectomy (removal of infected vitreous akin to draining an abscess) in the operating room if
Acute damage, and cause the peripheral iris to adhere to the trabecular lens (which is sustained by aqueous humor) may occur. Sustained retinal nerve fiber layer, and the avascular anterior portion of the ischemia to intraocular structures, particularly the optic nerve, (steamy) (Fig. 61.22). The IOP is significantly elevated, and an enlarged ratio of the diameter of the optic disc (termed cupping) and peripheral visual field loss. Glaucuoma usually but not always is associated with elevated IOP.

Primary open-angle glaucoma is a chronic condition characterized by asymptomatic elevated IOP (but IOP may not always be elevated), and an enlarged ratio of the diameter of the optic cup to the diameter of the optic disc (termed cupping) and peripheral visual field loss. Patients may be on chronic topical ophthalmic medications designed to improve aqueous outflow. It is not typically a cause for an urgent visit to the ED (and therefore not needed. The typical bacterial pathogen varies with the likely cause; coagulase-negative staphylococci are most common in post-cataract endophthalmitis, Bacillus cereus is a major cause of post-traumatic endophthalmitis, and S. aureus and streptococci are important causes of endogenous endophthalmitis associated with endocarditis.50

**ACUTE ANGLE-CLOSURE GLAUCOMA**

**Principles**

Aqueous humor provides structural support to the eye and delivers oxygen and nutrients to the avascular lens and cornea. It is produced by the ciliary processes, passes from the posterior chamber to the anterior chamber through the pupillary aperture, and then is transported into the trabecular meshwork located at the anterior chamber angle formed by the junction of the root of the iris and the peripheral cornea. This trabecular meshwork serves as a one-way valve and filter for the aqueous humor into the canal of Schlemm, which in turn drains into episcleral veins. IOP is determined by the rate of aqueous humor production relative to its outflow and removal, and it is normally between 10 to 20 mm Hg.

**Clinical Features, Differential Diagnosis, and Diagnostic Testing**

Glaucuoma is an acquired chronic optic neuropathy. It is characterized by an enlarged ratio of the diameter of the optic cup to the diameter of the optic disc (termed cupping) and visual field loss. Glaucuoma usually but not always is associated with elevated IOP. The two most common and important forms of glaucoma are primary open-angle glaucoma and acute angle-closure glaucoma.

Primary open-angle glaucoma is a chronic condition characterized by asymptomatic elevated IOP (but IOP may not always be elevated), and an enlarged ratio of the diameter of the optic cup to the diameter of the optic disc (termed cupping) and peripheral visual field loss. Patients may be on chronic topical ophthalmic medications designed to improve aqueous outflow. It is not typically a cause for an urgent visit to the ED (and therefore not discussed further), although it can lead to complete blindness over time.

Acute angle-closure glaucoma is the entity that typically precipitates an acute ED visit, at times in a patient with no prior knowledge or history of chronic glaucoma. A variety of rare conditions (such as, tumors, neovascular processes) can predispose a patient to this, but the more common predisposed patient has an anatomically shallow anterior chamber that further narrows with aging as the lens enlarges. Acute symptoms are often precipitated by pupillary dilation from being in a low-light environment (e.g., movie theater) or taking an anticholinergic or sympathomimetic medication. This transient contraction of the iris crowds the angle (“pupillary block”), and continued formation of aqueous leads to an increased IOP, causing the iris to bulge forward, further inhibiting outflow, and eventually compromising arterial flow into the eye. The patient with acute angle-closure glaucoma typically presents with severe unilateral eye pain, redness, and blurred vision with “halos,” as well as nausea and vomiting. On examination, the pupil may be moderately dilated and unreactive to light, the anterior chamber shallow when illuminated from the side with a penlight, the conjunctiva injected, and the cornea cloudy (steamy) (Fig. 61.22). The IOP is significantly elevated, and ischemia to intraocular structures, particularly the optic nerve, retinal nerve fiber layer, and the avascular anterior portion of the lens (which is sustained by aqueous humor) may occur. Sustained elevation in IOP can cause permanent corneal and optic nerve damage, and cause the peripheral iris to adhere to the trabecular meshwork, forming anterior synechiae and an irreversible occlusion that only can be corrected by surgery.

**Management and Disposition**

Treatment of acute angle-closure glaucoma begins with medications used to lower the IOP and then proceeds to definitive treatment of the anatomical abnormality that led to the elevated pressure in the first place.51 Emergent ophthalmology consultation is necessary, and the treatment paradigm in the ED is as follows:

- **Drugs that may be used to reduce production of aqueous humor:**
  - Topical beta-blocker (timolol 0.5%—1 to 2 gtt)
  - Carbonic anhydrase inhibitor (acetazolamide 500 mg IV or orally)
  - Systemic osmotic agent (mannitol 1 to 2 g/kg IV over 45 minutes, to minimize cerebral effects, and typically reserved if topical medications and acetazolamide do not work within 1 hour)
  - **Drugs that may be used to increase outflow:**
    - Topical alpha-agonist (phenylephrine 1 gtt)
    - Miotics (pilocarpine 1% to 2%)
  - **Topical steroid (prednisolone acetate 1%—1 gtt every 15 to 30 minutes four times, then every hour)**
  - **Definitive treatment—laser peripheral iridotomy within 24 to 48 hours**

**PRIMARY DISORDERS OF VISION**

**Principles**

The process of visual perception is an orchestration of light refraction through the cornea and lens, signal transduction by the retina to generate electrical impulses, and transmission of those impulses through the optic nerve to be processed in each occipital cortex, being split and crossed at the chiasm along the way (Fig. 61.23). Primary disorders of vision can be caused by a derangement in any component in this process and may present as blurred vision, a focal disturbance somewhere in the visual field (in the form of dark objects or floaters, flashing lights (photopsia), or a visual field cut), or frank vision loss. Double vision has a very distinct presentation and is comprehensively addressed in Chapter 18.

The history enables a tailored approach to the evaluation of a patient with an atraumatic visual disturbance but may be fraught with challenges. One is the potential for a patient to use the term blurred vision to actually describe double vision, and vice versa. Another is that the patient with a cortical visual field cut may not...
visual acuity or visual field loss, typically from dysfunction of the optic nerve on that side, with an APD on the side involved on swinging flashlight test (see Fig. 61.11), and a visual field defect that does not respect the vertical midline and is often localized to the center of the visual field. Patients with chiasmal and post-chiasmal visual loss will typically have preserved visual acuity, and a visual field loss in both eyes that respects the midline (see Fig. 61.23).

Blurred Vision: Optic Neuritis, Toxic and Metabolic Disturbances, and Papilledema

Clinical Features and Differential Diagnosis

Any disturbance in the refraction of light may cause the symptom of blurred vision. Considerations include corneal infiltrates (from infections), significant pupillary dilation (which results in an increase in the scattered of light rays reaching the lens), and changes in the refractive properties of the lens or vitreous (due to edema from rapid osmotic changes). Blurred vision may also result from transductive dysfunction from retinal or optic nerve inflammation or edema. Considerations in the differential diagnosis of blurred vision include optic neuritis (which is usually
Other potential causes of a toxic visual disturbance are barbiturates that also affect photoreceptors in the retina, leading to visual loss. In addition, it leads to widespread electrophysiological dysfunction of the optic nerve and leads to edema and compromised axoplasmic flow; in some instances, methanol is metabolized to formic acid, which accumulates in the optic nerve head. Although visual symptoms may be isolated on rare occasion, patients with these entities will typically present with headache, which will provoke their consideration. That being said, a small percentage of patients with pseudotumor cerebri present with isolated subjective visual loss, blurred vision, or enlargement of the physiologic blind spot as the initial presenting symptom of the disease, and rapid deterioration may occur over days in severe cases. Swelling of the optic disc and blurring of the disc margins, hyperemia, and loss of physiologic cupping are present. There may be obliteration of spontaneous venous pulsations. Flame-shaped hemorrhages and yellow exudates may appear near the disc margins as the edema progresses. Visual acuity may be affected as the swelling becomes severe. Papilledema is typically bilateral but may be asymmetrical.

### Optic Neuritis

Optic neuritis is a primary, autoimmune inflammatory process of the optic nerve, affecting mostly young patients (range, 15 to 45 years old), has an association with multiple sclerosis, and is the presenting symptom of multiple sclerosis in 25% of cases. The patient with optic neuritis typically presents with monocular blurring or fogginess of vision evolving over hours or days, mild or severe pain with movement of the involved eye if the lesion is within the orbit, and at times bright, fleeting flashes of light with eye movement, as well as worsening of vision with small increases in body temperature (from exercise, hot baths, or hot weather). The natural history of optic neuritis is for visual acuity to reach its poorest within 1 week and then slowly improve over the next several weeks. Approximately 30% of patients with acute optic neuritis develop multiple sclerosis within 5 years. Approximately 30% of patients with optic neuritis have a recurrence within 10 years of initial presentation.

With regards to toxic visual disturbances, perhaps the most characterized toxin is methanol presenting with acute visual change due to optic nerve toxicity. Orally ingested methanol (the toxicity of which is described in entries dedicated to it elsewhere in this text) is metabolized to formic acid, which accumulates in the optic nerve and leads to edema and compromised axoplasmic flow; in addition, it leads to widespread electrophysiological dysfunction that also affects photoreceptors in the retina, leading to visual loss. Other potential causes of a toxic visual disturbance are barbiturates, chloramphenicol, emetine, ethambutol, ethylene glycol, isoniazid, and heavy metals.

In terms of metabolic visual disturbances, any rapid osmolar shift in the cornea, lens, or even retina has the potential to cause visual changes. A representative scenario is acute hyperglycemia. A rapid elevation in blood glucose (or a rapid correction of severe hyperglycemia), as seen in poorly controlled diabetics, may cause an acute hyperopia (far-sightedness), presumably due to changes in refraction in the lens. It may alternatively cause acute myopia when the rise in intracellular glucose levels in the lens overwhelms the normal glucose metabolic pathway such that it is converted to less absorbable sorbitol and fructose, generating an acute hyperosmolar state and stromal swelling. This may be followed by acute bilateral cataract formation within a matter of hours to days. Metabolic visual disturbances can also be from a nutrition-related optic neuropathy from causes such as thiamine deficiency and pernicious anemia.

### Papilledema

Papilledema may be seen on examination and refers to changes in the optic disc from increased intracranial pressure. The subarachnoid space of the brain is continuous with the optic nerve sheath. Any increase in the cerebrospinal fluid pressure (such as, from pseudotumor cerebri syndrome [otherwise known as idiopathic intracranial hypertension], cryptococcal meningitis in HIV/AIDS patients, or hydrocephalus or intracranial mass) can be transmitted to the optic nerve, resulting in swelling of the optic nerve head. Although visual symptoms may be isolated on rare occasion, patients with these entities will typically present with headache, which will provoke their consideration. That being said, a small percentage of patients with pseudotumor cerebri present with isolated subjective visual loss, blurred vision, or enlargement of the physiologic blind spot as the initial presenting symptom of the disease, and rapid deterioration may occur over days in severe cases. Swelling of the optic disc and blurring of the disc margins, hyperemia, and loss of physiologic cupping are present. There may be obliteration of spontaneous venous pulsations. Flame-shaped hemorrhages and yellow exudates may appear near the disc margins as the edema progresses. Visual acuity may be affected as the swelling becomes severe. Papilledema is typically bilateral but may be asymmetrical.

### Toxic and Metabolic Visual Disturbances

A key component in the diagnostic approach to blurred vision from toxic and metabolic disturbances is recognizing the existence of a cause. These processes are bilateral, progressive, and symmetrical and may manifest with a drop in visual acuity, evident hazing in the lenses, or retinal edema on funduscopy. Visual loss can be severe and visual field testing reveals central defects. In each case, the treatment is aimed at the underlying toxin, metabolite, or deficiency involved (described in entries dedicated to them elsewhere in this text). Blurred vision due to hyperglycemia typically reverses when hyperglycemia is treated, although cataracts may sometimes be permanent.

**Papilledema.** The diagnostic evaluation and management of specific disease processes that result in bilateral papilledema can be found in entries specifically dedicated to them elsewhere in this text. An important part of the assessment is a funduscopic eye examination, with an assessment of the optic disc. Early or mild papilledema may be difficult to detect with the direct ophthalmoscope, and if the suspicion of such a process is high, consultation with ophthalmologist in the ED for stereoscopic viewing of the optic discs with indirect ophthalmoscope is recommended, and patients should undergo neuroimaging (either with MRI or contrast-enhanced CT).

### Visual Field Disturbances: Floaters, Flashes, and Field Deficits

#### Clinical Features and Differential Diagnosis

Visual field disturbances may take the form of floaters (seeing objects in the field of vision, caused by material obstructing the light path), photopsia (flashing lights, caused by aberrant stimulation of the retina), or field deficits (focal areas of visual loss, caused by dysfunction in the transport or processing of impulses sent by the retina). Photopsia may be unilateral or bilateral, depending on the cause. The most common causes of unilateral
photopsia are vitreous or retinal detachment (see later), with which abnormal mechanical stimulation of the retinal photoreceptors leads to a cascade of action potentials that the visual system interprets as flashes of light. A less common cause of unilateral photopsia is uveitis involving the choroid. The most common cause of bilateral (and homonymous) photopsia is migraines, although scintillating scotomata is much more frequent. Less common causes of bilateral homonymous photopsia include lesions of the visual cortex with release hallucinations or epileptic seizures.

Considerations in the differential diagnosis of these visual field disturbances include intraocular (monocular) entities such as vitreous hemorrhage, vitreous and retinal detachment, and extraocular (binocular) entities at the optic chiasm and beyond.

Vitreous hemorrhage results from bleeding into the pre-retinal space or into the vitreous cavity. The most common causes are diabetic retinopathy and retinal tears. Additional causes include neovascularization associated with branch vein occlusion, sickle cell disease, retinal detachment, posterior vitreous detachment, trauma, age-related macular degeneration, retinal artery microaneurysms, trauma, and intraocular tumor. Symptoms begin with dark floaters or “cobwebs” in the vision and may progress over a few hours to painless visual loss. Floaters, described by the patient as dark or black dots or strands moving in the visual field in the direction of the preceding eye movement, are caused by vitreous blood.
Vitreous detachment is a common occurrence in patients older than 60 years old. With aging, the vitreous gel desiccates, shrinks, and pulls away from the retina, leading to symptoms similar to those of vitreous hemorrhage and retinal detachment.

Retinal detachment can occur by three mechanisms: (1) rhegmatogenous, (2) exudative, and (3) tractional. The retina has two layers—the inner neuronal retina layer and the outer retinal pigment epithelial layer—that can be separated by fluid accumulation. A retinal tear in the retinal membranes may or may not lead to a retinal detachment. A rhegmatogenous retinal detachment occurs as a result of a tear in the neuronal layer, allowing fluid from the vitreous cavity to leak between and separate the two retinal layers. It occurs in patients older than 45 years old, is more common in men, and is associated with degenerative myopia. Trauma can cause this type of detachment at any age, with patients with severe myopia being at greater risk. An exudative retinal detachment occurs as a result of fluid or blood leakage from vessels within the retina and is associated with hypertension, pre-eclampsia, central retinal venous occlusion, glomerulonephritis, papilledema, vasculitis, and choroidal tumor. Finally, a tractional retinal detachment is a consequence of contraction of a fibrous band that has formed in the vitreous. With retinal detachment, patients typically note flashes of light related to the traction on the retina, floaters related to vitreal blood or pigmented debris, and visual loss. The visual loss is commonly described as filmy, cloudy, or curtain-like in appearance, and is painless.

If a visual field disturbance is binocular, then a chiasmal or cortical disorder should be considered. Chiasmal disease is most commonly caused by chiasmal compression from pituitary tumors, craniopharyngiomas, or meningiomas. Visual loss is gradual and progressive. Beyond the optic chiasm, the most common causes of visual disturbances are infarctions, tumors, arteriovenous malformations, and migraine disorders. Patients report difficulty in performing a certain task, such as reading. Lesions can be located from the immediate post-chiasmal optic tract to the occipital cortex.

Diagnostic Testing, Management, and Disposition

In the diagnostic evaluation of visual field disturbances, the history should be specific enough to ascertain if the problem is an issue of an absence of vision (ie, a “blind spot,” or visual field deficit, as seen in chiasmic or cortical etiologies), or of an obstruction of vision (ie, “floaters,” as seen in vitreous detachment or hemorrhage, or retinal detachment). In addition, a visual field examination should be detailed enough to determine if the disturbance is monocular or binocular and whether it respects the midline. Funduscopy is especially important to enable an assessment of the vitreous and retina, and ocular ultrasound is a helpful adjunct. With this approach, the considerations outlined earlier can be differentiated and addressed.

Vitreous Hemorrhage and Detachment. With a vitreous hemorrhage, direct ophthalmoscopy reveals a reddish haze in mild cases and a black reflex in severe cases. Details of the fundus are usually difficult to visualize. There is a diminished red reflex and an inability to visualize the fundus clearly with the direct ophthalmoscope. Ocular ultrasound, which will reveal echogenic debris in the vitreous, can be an effective diagnostic screening tool (Fig. 61.26A). A vitreous hemorrhage or detachment usually does not cause an APD by itself, and if an APD is present, an occult retinal detachment may be present. A hemorrhage may be evenly distributed throughout the vitreous, or—if trapped in the subhyaloid space as a pre-retinal hemorrhage—may be focal, with a boat shape (see Fig. 61.26B).

Ophthalmologic consultation in the ED, or a same-day evaluation by an ophthalmologist, will typically be needed to characterize the extent and complications of any suspected vitreous hemorrhage or detachment and manage vision-threatening complications. The management of a vitreous hemorrhage is otherwise largely expectant, with limitation of activity, avoidance of anticoagulants, and sleeping with the head of bed elevated to allow blood to settle and optimize visualization of the retina on subsequent examinations. Surgery is typically required if there is an associated retinal detachment. The same consideration applies for a posterior vitreous detachment, for which no specific emergent treatment is indicated unless accompanied by a retinal tear, vitreous hemorrhage, or retinal detachment.

Retinal Detachment. With a retinal detachment, visual acuity can range from minimally changed to severely decreased. Visual field deficits relate to the location of the retinal detachment, and an APD occurs if the detachment is large enough. When the detachment is visible on ophthalmoscopy, the retina appears out of focus at the site of the detachment. In large retinal detachments with large fluid accumulation, a bullous detachment with retinal folds can be seen (Fig. 61.27A). Retinal detachment cannot be ruled out by direct funduscopy. Indirect ophthalmoscopy is needed to visualize the more anterior portions of the retina. Bedside ED ultrasonography can be a useful tool in screening for a retinal detachment (see Fig. 61.27B). It will reveal a billowing hyperechoic line that may undulate with side-to-side movements of the eye.
Any patient suspected of having a retinal tear or detachment requires immediate ophthalmologic consultation, because treatment with tamponade or retinopexy can prevent a retinal detachment that does not involve the macula (a “macula-on” retinal detachment) from progressing to involve the macula (“macula-off”) and significantly degrade visual acuity. The duration of macular detachment, measured from the reported time of the loss of central visual acuity, is inversely related to final visual acuity. Even though the literature suggests that there is almost a day’s-worth of leeway in the timing of repair of a “macula-on” detachment, and a fair amount of visual acuity is recoverable if a “macula-off” detachment is repaired early enough, a “macula-on” detachment that is close to the macula is at risk of converting to “macula-off” with even a few hours delay.

Chiasmal and Cortical Disturbances. Although formal visual field testing may be necessary to stage the condition, the diagnosis of a chiasmatic or cortical etiology to a visual field disturbance can usually be made by confrontation visual field testing. The classic defect for a lesion in or compression of the optic chiasm (chiasmal) is a bitemporal hemianopsia; however, tumors often compress the chiasm and optic nerves asymmetrically, resulting in combined central and temporal defects. When a visual field defect respects the vertical midline, the lesion is out of the globe and likely either chiasmal or post-chiasmal (see Fig. 61.23).

The classic visual field defect in post-chiasmal (cerebral or cortical) disease is a homonymous hemianopsia, a visual field loss on the same side of both eyes (see Fig. 61.23). Patients with such lesions have a focal neurologic deficit and need to be evaluated and treated based on the primary neurological diagnostic considerations, which include occipital infarction, neoplasm, an inflammatory process, or an infectious process (such as, encephalitis).

### Sudden Vision Loss: Retinal Artery and Vein Occlusion, and Ischemic Optic Neuropathy

#### Clinical Features and Differential Diagnosis

Sudden onset of atraumatic, vision loss is usually due to a vascular process, such as infarction (although nonvascular processes, such as from retinal detachments and hemorrhages affecting the macula, are possible). Binocular processes include a sudden homonymous hemianopsia from an infarction of the visual pathways in the temporal, parietal, or occipital lobes; and sudden total blindness in both eyes due to a basilar artery territory infarction of both occipital lobes. Central nervous system (CNS) processes (such as, ischemic stroke) that underlie these binocular events are discussed in entries specific to them elsewhere in this text. This section is, therefore, dedicated to sudden onset of painless monocular vision loss, which is ophthalmological and is usually due to a vascular process, such as infarction in either the retina or the optic nerve; the differential diagnosis primarily includes central retinal artery occlusion (CRAO), central retinal vein occlusion (CRVO), and ischemic optic neuropathy (ION). These typically present with sudden vision loss that is painless, severe, and develops over seconds, and may be permanent, or transient (amaurosis fugax).

In a CRAO, acute retinal ischemia develops from a sudden embolic, thrombotic, vasculitic or vasospastic occlusion of a branch of the retinal artery (a branch retinal artery occlusion [BRAO]) or the central retinal artery itself (a CRAO). A CRAO may be (1) non-arteritic and permanent (over two-thirds of all CRAO cases, due to platelet fibrin thrombi and emboli from atherosclerotic disease), (2) non-arteritic and transient (with transient monocular blindness, a transient ischemic attack [TIA] of the retina, related to transient vasospasm due to serotonin release from platelets on atherosclerotic plaques), or (3) arteritic (due to temporal arteritis and rare). It generally has a poor visual prognosis with spontaneous resolution occurring in 1% to 8% of cases. Most commonly occurring in patients 50 to 70 years old, CRAO risk factors include hypertension, carotid artery disease, cardiac disease, diabetes, collagen vascular disease, vasculitis, cardiac valvular abnormality, and sickle cell disease. Patients with increased orbital pressure from acute glaucoma, retrobulbar hemorrhage, and endocrine exophthalmos are also at risk.

A CRVO leads to congestion of venous blood and fluid in the intraretinal space that may lead to secondary retinal ischemia. It is characterized as either non-ischemic or ischemic; a non-ischemic CRVO is associated with dilatation of retinal vessels and edema only, whereas an ischemic CRVO presents with the sudden onset of painless vision loss in one eye. Predisposing factors include hypertension, hyperlipidemia, diabetes mellitus, vasculitides, hyperviscosity, and smoking.

ION falls into two primary types, anterior ischemic optic neuropathy (AION; involving the optic nerve head) and posterior ischemic optic neuropathy (PION; involving the rest of the optic nerve). AION can further be divided into arteritic anterior ischemic optic neuropathy (A-AION; due to temporal arteritis) and—more commonly—non-arteritic anterior ischemic optic neuropathy (NA-AION; due to noninflammatory causes).

Patients with A-AION may have concurrent symptoms of temporal arteritis (giant cell arteritis), such as weight loss, malaise, jaw pain, headache, scalp tenderness, polymyalgia rheumatica, and low-grade fever; in up to 25%, however, the acute vision loss is the only symptom. Vision loss can be preceded by episodes of amaurosis fugax. Untreated it may progress to involve both eyes. Temporal arteritis is extremely rare in people younger than 50.
years old, and the incidence rises with each subsequent decade. Vision loss has been shown to be unilateral in 46%, sequential in 37%, and simultaneously bilateral in 17%.

Patients with the much more common NA-AION lack the classic symptoms of temporal arteritis and tend to be younger with systemic vascular disease, diabetes, or hypertension. This is an acute ischemic event affecting the anterior optic nerve that typically occurs in patients over the age of 50 (typically 60 to 70 years old), at times associated with precipitant anemia, hypovolemia, dehydration, systemic hypotension, or fluctuations in blood pressure (especially that associated dialysis). A sudden complete loss of vision due to a vascular cause can be transient, whereupon it is called amaurosis fugax, and can be a manifestation of any of the aforementioned processes. It has been found in 2% of CRAO, 14% of BRAO, 5% of CRVO, just over 3% in NA-AION, and in 32% of patients with temporal arteritis who have ocular involvement. Amaurosis fugax may also implicate proximal cerebrovascular disease and be a form of transient ischemic attack.

Diagnostic Testing, Management, and Disposition

Central Retinal Artery Occlusion. With CRAO, the examination reveals a markedly reduced visual acuity with a prominent APD, and an edematous with a pale gray-white retina with a cherry-red spot representing the fovea seen on funduscopy (Fig. 61.28). Patients younger than 50 years old should have a hypercoagulability evaluation, whereas older patients at risk for temporal arteritis should have an evaluation appropriate for that consideration.

A number of interventions geared toward dislodgement of the embolus (via direct digital pressure through closed eyelids for 10 to 15 seconds and followed by a sudden release), dilation of the artery to promote forward blood flow (by increasing intra-arterial carbon dioxide level [pCO₂] with an inhaled mixture of 95% oxygen/5% carbon dioxide [carbogen]), and reduction of IOP (such as, with glaucoma, even using anterior chamber paracentesis) to increase in perfusion gradient have been recommended, but there is little evidence to support the benefit of any of these treatments. Other options include hyperbaric oxygen. Overall, the efficacy of the above therapies varies between 6% and 49%, with a mean visual improvement rate of 15% to 21%.

A CRAO may be amenable to the use of thrombolytic agents, with the caveat that it is usually an atheromatous embolic event, and thrombolysis is designed to lyse the fibrinoplatelet occlusion in a non-arteritic CRAO. Studies are heterogeneous, using different agents, dosing regimens, and time-windows in largely retrospective case series with different findings, but it appears that intra-arterial thrombolytic therapy might be effective if given less than 6 hours from onset. IV thrombolysis might be effective if given less than 4.5 hours from onset, with a post-thrombolysis major hemorrhage rate significantly lower than that seen with ischemic stroke (none documented with tissue-plasminogen activator or urokinase). Until a large randomized controlled trial of the safety and efficacy of thrombolysis for CRAO is performed, management should be tailored to individual patient circumstances in consultation with an ophthalmologist.

Central Retinal Vein Occlusion. A CRVO is differentiated from CRAO based on findings on funduscopic examination. Appearance can vary but classically includes dilated and tortuous veins, retinal hemorrhages, and disk edema (Fig. 61.29). Branch retinal vein occlusion is an incomplete CRVO and carries about a better prognosis. Neovascular glaucoma and macular edema are the major complications of ischemic CRVO.

Over 80% of patients with a non-ischemic CRVO will have an ultimate visual acuity that is better than 20/200, whereas less than 10% of patients with ischemic CRVO will have an ultimate visual acuity better than 20/200. Treatment of CRVO includes treating the underlying etiology and monitoring for potential sequelae. Ophthalmology should be consulted in the ED to secure timely initiation of therapy, which largely centers around treating the macular edema associated with the occlusion. Treatment involves anti-vascular endothelial growth factor (anti-VEGF) pharmacotherapies, intravitreal corticosteroid injection with a dexamethasone intravitreal implant or triamcinolone, as well as retinal photocoagulation, normalization of IOP, and cyclocryotherapy. The use of antithrombotic therapy, in particular the use of low-molecular-weight heparin, has also shown recent promise. Underlying medical disease should be managed;
the prognosis depends on the degree of obstruction and resultant complications.

Ischemic Optic Neuropathy. Examination findings are similar in A-AION and NA-AION, and include a large APD, visual loss, and a visual field defect that may respect the horizontal (as opposed to vertical) midline, with a pale and swollen optic disc on funduscopy.

The diagnosis of a temporal arteritis underlying an A-AION is outlined in entries specific to it elsewhere in this text, and it may include an erythrocyte sedimentation rate (ESR). Patients with NA-AION, on the other hand, do not have an elevated ESR, and an MRI may reveal abnormalities to the optic nerve head.

Temporal arteritis with evolving vision loss or amaurosis fugax from A-AION—as opposed to just headache alone—represents a distinct clinical emergency. Untreated, vision loss becomes bilateral in days to weeks in at least 50% of cases. Patients should therefore be admitted for high-dose IV methylprednisolone (typically 500 mg to 1 g daily for 3 days) before transition to oral medications. Patients treated with high-dose IV methylprednisolone are more likely to have visual improvement (a 34% chance of improvement) and are less likely to develop fellow eye involvement than those receiving oral prednisone.

The visual loss in NA-AION is less severe than with temporal arteritis, and improvement occurs in one-third of patients. There is no known treatment (intravitreal and systemic steroids have been tried without success, as have anti-VEGFs). Emergent ophthalmological consultation in the ED is warranted for any apparent ION to aid with differentiation of the type and extent of the process and management.

Functional Vision Loss

Clinical Features, Differential Diagnosis, Diagnostic Testing, Management, and Disposition

Functional (or factitious) vision loss may be a hysterical conversion reaction (a non-deliberate, imagined visual loss in a patient with a relatively flat affect) or malingering (a vision loss for secondary gain in a patient who somewhat dramatically demonstrates blindness). Although the evaluation may require collaborative consultation with an ophthalmologist, neurologist, and a psychiatrist, some tests can be performed in the ED that will suggest a functional overlay, given that the most common presentation of functional vision loss is a decreased visual acuity. They include (1) rotating an optokinetic drum or rocking a mirror slowly back and forth in front of the patient (which will induce nystagmus or eye movements in the functional patient, but not in the truly blind patient), (2) rapidly moving the examiners hand toward the eye in question (which will induce a blink to a visual threat in the functional patient, but not in the truly blind patient), (3) checking for an APD as in Figure 61.11 (which will be absent in the functional patient but not in the truly blind patient with an optic nerve problem), (4) having the patient raise his or her arms and touch both index fingers together (which a functional patient will feign inability to do, but a truly blind patient will be able to do, given that the test is actually one of proprioception and not vision). The other presentation of functional visual loss is a defect in the visual field, typically with a central scotoma. This can be identified as functional by having the patient sit in front of a picture (or grid) and describe the extent of a visual field defect vis-à-vis what is missing, and then moving him or her further away and asking for another description of what is missing. The functional patient may describe same missing elements in the picture (in an effort to convince the examiner that the defect is stable), whereas the patient will a real visual field deficit will notice that more elements in the picture (or grid) are missing.

DIPLOPIA

Chapter 18 provides a comprehensive overview of the approach to diplopia in the ED expounding on a methodological consideration of whether a binocular diplopia is due to an due to (1) a simple restrictive, mechanical orbitopathy from inflammatory or infectious mass-effect directly restricting of the movement of the eye, (2) a palsy of one or more of the oculomotor CNs, (3) a more proximal neuro-axial process involving the brainstem and related CNs, or (4) a systemic neuromuscular process.

ANISOCORIA

Principles

Dilation (mydriasis) of the pupil is controlled by the dilator muscle, innervated by sympathetics that exit spinal cord at the level of C8, T1, and T2, and then come back up under the subclavian artery and over apices of the lungs, enter the superior cervical ganglion, then the internal carotid plexus, and finally the ophthalmic division of CN V (the trigeminal nerve), whereupon they reach the eye through the superior orbital fissure. This sympathetic innervation serves a largely inhibitory role, facilitating pupillary dilation in darkness.

Constriction (or miosis) of the pupil is controlled by the pupillary sphincter muscle, innervated by parasympathetics that originate in the nuclei of CN III. This parasympathetic innervation is the primary means of regulating pupillary size in response to different intensities of light. Afferent input from the retina of each eye bifurcates to innervate the Edinger Westphal nuclei of each CN III, and each nucleus in turn provides efferent output to its pupillary constrictor muscle, underlying the direct and consensual pupillary light reflexes. Anisocoria, or a difference in pupillary size, can result from a process affecting the nuclei or the innervation pathways or from pharmacological interference at the neural endplates in the pupillary muscles.

Clinical Features and Differential Diagnosis

The differential diagnosis of anisocoria include an Adie’s or Argyll Robertson pupil, pharmacologic mydriasis and miosis, a third-nerve palsy, Horner’s syndrome, and a physiologic or headache-associated anisocoria.

Adie’s and Argyll Robertson Pupils

An Adie’s tonic pupil results from dysfunction or lesion of the ciliary ganglion or short ciliary nerves, and may be idiopathic (seen more frequently in women than men), for from local ocular or orbital damage from surgery, trauma, procedures, infection, inflammation, or ischemia. An Adie’s tonic pupil may also be part of a condition causing systemic autonomic dysfunction, such as diabetes, dysautonomia, neurosyphilis, amyloidosis, or sarcoidosis. These patients present with a large pupil, sensitivity to light in that eye, and blurred vision when looking at things near them (but may be asymptomatic, with the pupil noticed incidentally). The Argyll Robertson pupil is typically smaller than an Adie’s and similarly constricts poorly to direct light, but it briskly constricts when a target within reading distance is viewed. It is attributable to a dorsal midbrain lesion (such as from neurosyphilis) that interrupts the pupillary light reflex pathway but spares the more ventral pupillary near reflex pathway.

Pharmacologic Mydriasis and Miosis

Anisocoria can be caused by a variety of accidental medication and plant exposures. Parasympathomimetic miosis may be
induced by exposures to organophosphate esters, pilocarpine drops, or dust containing cholinesterase inhibitor from a dog’s flea collar. Parasympatholytic mydriasis may be seen with anticholinergic medications (such as, transdermal scopolamine), aerosolized ipratropium administered through ventilator masks, cycloplegics (such as, homatropine, cyclopentolate, or tropicamide), and plants containing anticholinergic agents, such as Jimsonweed (Datura stramonium) and Angel’s trumpet (Datura suaveolens). Sympathomimetic mydriasis may occur from sprays containing phenylephrine (Neo-Synephrine) and from apraclonidine (a glaucoma medication).

**Physiologic and Headache-Associated Anisocoria**

In physiological anisocoria, the difference in pupil size will typically be 1 mm or less. A more prominent transient mydriasis (benign episodic unilateral mydriasis) may occasionally accompany a migraine headache, either from sympathetic hyperactivity, or—with an ophthalmoplegic migraine—parasympathetic hyperactivity from CN III dysfunction. A non-migrainous benign episodic unilateral mydriasis can occur without headache, ptosis, or ocular motility disorder, in episodes lasting minutes, hours, or even days and is also thought to be caused by over-activity of sympathetic innervation to the pupil. Patients are typically female, relatively young, and episodes last a median duration of 12 hours.

Patients can also present with a “tadpole pupil,” in which the pupil becomes distorted and pulled in one direction like the tail of a tadpole, possibly occurring several times a day for several days and then resolving. This is likely the result of a sectoral spasm of the dilator muscle, thought to be benign, and has been associated with strenuous exercise. If, on the other hand, the patient has a baseline anisocoria and the tadpole pupil manifests in the smaller of the pupils, testing for Horner’s syndrome is recommended.

**Diagnostic Testing, Management, and Disposition**

Determination of the potential etiology of an anisocoria can be facilitated by the approach outlined in the explanatory algorithm in Figure 61.30. Assuming no damage to the iris (implying a purely structural problem) is evident on slit-lamp examination, the strategy is to differentiate a benign cause of anisocoria (eg, physiological or pharmacological) from one that requires additional neuro-ophthalmological consultation (eg, Horner’s syndrome) or emergent neuro imaging (eg, CN III compression potentially due to an aneurysm). The first step is to determine which pupil—the larger or the smaller—is the pathological one, keeping in mind that that parasympathetic innervation constricts a pupil in bright light, whereas sympathetic stimulation helps dilate a pupil in the dark. The subsequent steps incorporate the principles that an abnormally large pupil may be due to either a decrease in parasympathetic stimulation or an augmentation of sympathetic stimulation, and an abnormally small pupil may be due to either a decrease in sympathetic stimulation or an augmentation of parasympathetic stimulation.

The type of response to a topical application of cocaine (which specifically blocks norepinephrine uptake) can be diagnostic of Horner’s syndrome, in that with no norepinephrine available to block the re-uptake, the Horner’s pupil will typically not dilate. Other medications, such as hydroxyamphetamine (an

Fig. 61.30. The approach to anisocoria in the emergency department (ED), an explanatory algorithm.
*Some authors advocate that a marked response to low concentration (0.1% or 0.125%) pilocarpine is more consistent with an Adie’s pupil and can be used to differentiate it from an acute third nerve palsy (which may require the more concentrated 1% to elicit a reaction). This approach may be impractical, however, as a sole means to rule out a third nerve palsy from something like an aneurysm.
indirect-acting adrenergic mydriatic that causes endogenous norepinephrine to be released from sympathetic nerve endings without directly stimulating the effector cells, as well as direct adrenergic agonists, such as a phenylephrine or 1% apraclonidine, can be used with ophthalmological consultation to perform a secondary evaluation of a Horner’s pupil. Pilocarpine is a direct cholinergic receptor agonist and is used to differentiate hypoparasympathetic conditions (see Fig. 61.30).

Once one of the typical presentations of anisocoria is identified, the evaluation progresses based on the clinical indications. Examination of an Adie’s pupil typically reveals poor reaction to light with sectoral palsy of the iris sphincter, and a lack of (or slow) constriction with near accommodation (at least in the acute phase; later on, with re-inervation, the pupil will constrict strongly, and will thus be a “tonic” pupil). Slit-lamp examination may reveal sectoral palsies of the iris, and a weak cholinergic agent (pilocarpine 0.1%) causes an intense pupillary constriction (compared to the patient’s normal pupil) as a result of the cholinergic supersensitivity in the affected pupil. These patients should be referred non-emergently to an ophthalmologist for further evaluation. The Argyll Robertson pupil, like the Adie’s pupil, will demonstrate segmental, slow, or little iris sphincter constriction with light, but normal constriction with near accommodation (“light-near dissociation,” which distinguishes it from an acute Adie’s pupil). A patient with bilateral Argyll Robertson pupils should be screened for neurosyphilis as per standard (please refer to entries dedicated to syphilis elsewhere in this text). The patient with a new-onset Horner’s syndrome should undergo an evaluation to determine the cause and will typically require targeting imaging based on the diagnostic considerations outlined in Table 61.2, with MRI for brain, skull-base, and spinal cord lesions, and computed tomography angiography (CTA) for chest and neck/carotid pathology. The cadence of the evaluation (and which components are done in the ED) will be dictated by the acuity of the primary considerations in the differential diagnosis, with aneurysm, dissection, brainstem stroke, and a rapidly progressive myelopathic process evaluated emergently in the ED and a more subacute or chronic process (such as, a tumor) being worked up urgently as an outpatient. The diagnostic evaluation and management of a third nerve palsy is covered in Chapter 18 and Chapter 95. With regards to pharmacologic mydriasis and miosis, most of the exposures and their effects will be self-limited and transient, and the specific management will dictated by the toxicological sequelae expected. The first-time clinical presentation of physiological and headache-associated anisocoria (mydriasis) may provoke a neuro-imaging evaluation for the presence of aneurysmal or mass compression of CN III; although this is being excluded, treatment can be rendered along lines that are standard for migraine headache. Physiological and headache-associated anisocoria is otherwise self-limited and will not typically require urgent ophthalmology referral unless persistent.

**Nystagmus**

**Principles**

Three specific mechanisms keep an object of visual interest on the fovea: (1) fixation, wherein the visual system detects retinal drifts and programs corrective eye movements; (2) the vestibulo-ocular reflex (VOR), which keeps the eyes on target despite head movements; and (3) eccentric gaze-holding, which requires ongoing signals from the brainstem and cerebellum to overcome the natural elastic pull of orbital tissues when the eyes are deviated away from the mid-position to fixate on a target. Dysfunction in any of these three mechanisms removes the visual target from the fovea and may result in nystagmus and oscillopsia (a subjective sense of movement of the visual field).

Nystagmus is a repetitive horizontal, vertical, or torsional back and forth movement of the eyes that may appear as an equal “to and fro” motion (pendular nystagmus), or demonstrate an alternating, slow phase followed by a corrective fast phase (jerk nystagmus). In jerk nystagmus, although the slow phase is the abnormal one, the directionality of the nystagmus is described as that of the fast phase. Gaze-evoked nystagmus (GEN) is an ability to hold the eyes in a fixed position at the eccentric extremes of gaze.

Nystagmus can be physiologic or pathologic and congenital or acquired. Patients may have an incidental nonspecific physiologic nystagmus with a very small amplitude and a very fast velocity, non-sustained (less than three beats), only elicited in extreme eccentric gaze, only horizontal and symmetric, and without other signs or symptoms of cerebellar system dysfunction. A patient may also have congenital nystagmus, typically identified as chronic or present since birth, which requires no acute intervention in the ED. The focus in the ED is therefore on acquired pathological nystagmus, of which the etiologies can be classified as either (1) peripheral (such as, seen with benign peripheral vertigo or vestibular neuronitis), (2) central (such as, seen with ischemic stroke or CNS mass lesions), or (3) toxic and metabolic (such as, that induced by medications, alcohol or illicit drugs). The clinical priority is to distinguish a peripheral (which is relatively benign and can be treated as an outpatient) from central (which may imply focal CNS pathology and require targeted neuro-imaging) from toxic or metabolic etiologies (which may imply toxic levels of a medication, or an underlying illicit drug intoxication).

**Clinical Features, Differential Diagnosis, Diagnostic Evaluation, Management, and Disposition**

**Peripheral Nystagmus and Central Nystagmus**

Because peripheral and central nystagmus from lesional processes (e.g., from otoconia, vestibular neuronitis, posterior circulation stroke, brain tumor, and so on) present with prominent vertigo, a detailed discussion of these entities is deferred to the entries on vertigo and dizziness in Chapter 16. Table 61.3 highlights the specific features of the nystagmus associated with these conditions. The key clinical goal in the ED with regards to nystagmus is to distinguish a peripheral (which is relatively benign and can be treated as an outpatient) from central (which may imply focal CNS pathology and require targeted neuro-imaging) from toxic or metabolic etiologies (which may imply toxic levels of a medication, or an underlying illicit drug intoxication).

**Toxic and Metabolic Nystagmus**

Nystagmus from drug or medication toxicity may be suggested by a concurrent toxidrome and, depending on the agent and the degree of toxicity, a lack of prominent vertigo or ataxia (keeping in mind that the specificity of nystagmus findings as an indicator of toxicity is unknown). Drug-induced GEN, although symmetric, is different from physiological nystagmus in that it has a larger amplitude and slower velocity and beats in the direction of the gaze (i.e., upbeat nystagmus with the patient looking up, rightward nystagmus with the patient looking to the right, and so on). GEN from a focal cerebellar or brainstem lesion may look similar to that which is drug-induced, but it is characterized by a sustained asymmetric and rebound nystagmus in which, although the slow phase is directed toward primary position where the eyes are deviated, a few slow phases may be directed toward the prior gaze direction after the eyes return to the primary position. The management is targeted toward the overall toxicological profile of the specific offending agent.

KEY CONCEPTS

- Routine prophylactic topical antibiotics are not indicated for the treatment of corneal abrasions, and eye patches are not recommended because they can mask a worsening infection.
- Eyelid lacerations that may require referral to a plastic or ophthalmic surgeon include those with lid margin lacerations, a canalicular laceration, or levator or canthal tendon injuries.
- Alkaline burns to the cornea and conjunctiva need to be copiously irrigated until a neutral pH is attained, because they produce a liquefactive necrosis that penetrates and dissolves tissue.
- Admission should be considered for traumatic hyphema patients with sickle cell trait, uncontrolled elevations in intraocular pressures (IOPs), hyphema of greater than 50%, and concern for re-bleeding.
- Any manipulation, palpation, or tonometry on a suspected globe rupture should be avoided, pending ophthalmological consultation and further examination.
- Scleritis, an autoimmune inflammatory process involving the sclera, can be confused with episcleritis, caused by inflammation in the more superficial episcleral layer of the eye. Episcleritis, unlike scleritis, is associated with much less discomfort, a pinker and more pronounced peri-limbal injection, and has injected superficial episcleral vessels that—unlike the deeper injected scleral vessels in scleritis—will vasoconstrict and blanch with 10% phenylephrine. Treatment of both involves topical corticosteroid drops.
- Endophthalmitis is an infection of the eye itself, and the most common etiology is recent intraocular surgery. Intravitreal antibiotics are indicated for endophthalmitis.
- Herpes zoster keratoconjunctivitis can complicate herpes zoster ophthalmicus, and necessitates emergent ophthalmologic consultation and treatment with systemic antiviral agents.
- The acute treatment of acute angle-closure glaucoma uses a two-armed approach; (1) reducing the production of aqueous humor with a topical beta-blocker (timolol 0.5%—1 to 2 gtt), a carbonic anhydrase inhibitor (acetazolamide 500 mg IV or PO), and a systemic osmotic agent (mannitol 1 to 2 g/kg IV); and (2) increasing the outflow of aqueous humor with a topical alpha-agonist (phenylephrine 1 gtt), miotic drops (pilocarpine 1% to 2%), and topical steroids (prednisolone acetate 1%, 1 gtt every 15 to 30 minutes four times, then every hour).
- With anisocoria, the following considerations help in the determination of which pupil—the larger or the smaller—is the pathological one: (1) parasympathetic innervation constricts a pupil in bright light, whereas sympathetic stimulation helps dilate a pupil in the dark; (2) an abnormally small pupil may therefore be due to a either a decrease in sympathetic stimulation or an augmentation of parasympathetic stimulation—but likely the former (eg, Horner’s syndrome); (3) an abnormally large pupil may therefore be due to a either a decrease in parasympathetic stimulation or an augmentation of sympathetic stimulation—but likely the former (eg, partial third-nerve pals from compression, Adie’s pupil, pharmacological mydriasis); or (4) the abnormally small pupil will usually look worse in the dark, whereas the abnormally large pupil will usually look worse in the light.
REFERENCES

CHAPTER 61: QUESTIONS & ANSWERS

61.1. A 23-year-old male presents with left periorbital pain after being struck by a fist. On examination, there are no globe injuries but marked periorbital swelling is noted. Computed tomography (CT) of the face reveals an orbital floor fracture. Which of the following would be the most likely physical findings?
A. Cheek anesthesia, enophthalmos, and limitation of upward gaze
B. Cheek anesthesia, ptosis, and limitation of inferior gaze
C. Forehead anesthesia and afferent papillary defect
D. Forehead anesthesia, diplopia, and limitation of lateral gaze
E. Ptosis, miosis, and ipsilateral anhydrosis

Answer: A. An orbital floor fracture may entrap the inferior rectus and inferior oblique muscles, resulting in diminished upward gaze. Other findings may include ptosis, enophthalmos, ipsilateral cheek/lip anesthesia, and orbital emphysema. Ten percent to 25% of such patients have associated globe injuries. Option E describes Horner’s syndrome, which is not a typical finding.

61.2. A 20-year-old male presents with peri orbital pain and swelling after a blow to the eye by a softball. Physical examination reveals propptosis with blurred vision and limitation of ocular motion in all planes. Tonometry reveals an intraocular pressure (IOP) of 35 mm Hg. Which of the following should be the first indicated maneuver?
A. Acetazolamide 500 mg IV, mannitol 20 g IV, and topical timolol
B. Computed tomography (CT) scan of the head and face
C. Endotracheal intubation and hyperventilation
D. Immediate lateral canthotomy and cantholysis
E. Ophthalmologic consultation

Answer: D. These findings should make one suspect retrobulbar hemorrhage. All of these interventions are likely indicated. Intraocular hypertension may compromise central retinal artery flow. Although immediate ophthalmologic consultation and pressure lowering maneuvers are indicated, lateral canthotomy and cantholysis will provide the most rapid temporizing measure to preserve vision.

61.3. A 43-year-old male presents with acute ocular pain after a splash injury from drain cleaner. What should be the sequence of interventions?
A. Copious irrigation for 10 minutes, pH testing, cyclopentolate cycloplegia, topical antibiotics/ intraocular pressure (IOP) measurement
B. Intravenous (IV) analgesia, cyclopentolate cycloplegia, IOP measurement, isotonic irrigation
C. IOP measurement, analgesia, head-up position, cycloplegia
D. Phenylephrine cycloplegia, isotonic irrigation for 10 minutes, pH testing, slit-lamp examination for foreign bodies
E. Phenylephrine cycloplegia, slit-lamp examination for foreign bodies, isotonic irrigation for 10 minutes, pH testing

Answer: A. Copious irrigation, ideally beginning at the scene, is the cornerstone of management. Nitrazine pH testing after 10 minutes should guide the need for continued irrigation. Cyclospedia, IOP measurement, and topical antibiotics come after pH normalization. Phenylephrine is contraindicated for cycloplegia in these cases because of its vasoconstrictive properties.

61.4. A 17-year-old girl who wears contact lenses presents with a 24-hour history of right eye pain. Physical examination reveals a right corneal abrasion at the six-o’clock position of the limbus. Appropriate treatment consists of which of the following?
A. Cessation of contact lens wear, eye irrigation (qid) with isotonic saline solution, followed by instillation of undiluted topical tetracaine for 5 days
B. Emergent ophthalmology consultation
C. Tetanus prophylaxis, eye patching for 48 hours, antibiotic ointment, and a 24-hour recheck
D. Tetanus prophylaxis, topical nonsteroidal anti-inflammatory drugs (NSAIDs), cessation of contact lens wear, and a 24-hour recheck
E. Topical nonsteroidal medications, topical antipseudomonal antibiotic, and a 24-hour recheck

Answer: E. Tetanus prophylaxis is not indicated for corneal abrasion unless there is corneal perforation or contamination with organic material. Topical NSAIDs reduce corneal abrasion pain. Antipseudomonas coverage with cessation of contact lens wear is appropriate. Eye patching is not indicated. Administration of undiluted topical anesthetics for more than 24 hours is untested and may be dangerous. Oral analgesics may be needed.

61.5. How do patients with subconjunctival hemorrhage most commonly present?
A. Asymptomatic blood in the eye, noticed in the mirror or by a friend
B. Decreased visual acuity
C. Foreign body sensation
D. Modest pain
E. Photophobia

Answer: A. Any significant symptoms, such as pain, decreased vision, foreign body sensation, or photophobia, should spark the search for more serious pathology. Bilateral hemorrhage in the absence of a clear cause (eg, severe vomiting) should raise suspicion for coagulation issues.

61.6. A 38-year-old man presents with unilateral left-sided visual loss after a motor vehicle collision (MVC). The only clinical finding is a left-sided hyphema rising to 50% of the height of the anterior chamber. Intraocular pressure (IOP) is 17 mm Hg in the affected eye and 29 mm Hg in the affected eye. Appropriate management should include which of the following?
A. Cycloplegia, intravenous (IV) mannitol, ophthalmology consultation
B. IV analgesia and antibiotic, immediate ophthalmologic consultation for decompression resulting from intraocular hypertension
C. Oral acetazolamide, patch and shield, antiemetics, 24-hour recheck
D. Topical beta-blocker, patch and shield, modest analgesia, admission
E. Topical beta-blocker, topical nonsteroidal anti-inflammatory drugs (NSAIDs) for pain, patch and shield, 24-hour recheck

Answer: D. Significant hyphema is an indication for admission. The presence of elevated IOP requires urgent treatment (which might also include topical alpha-agonists or IV acetazolamide,
CHAPTER 61  Ophthalmology

and so on), patch and shield, elevation of the head, and cautious use of systemic analgesics. Any form of platelet inhibition would be contraindicated (ie, NSAIDs).

61.7. What is the major complication of hyphema?
A. Detached retina
B. Glaucoma
C. Horner’s syndrome
D. Rebleeding
E. Vitreous hemorrhage

Answer: D. Rebleeding typically occurs 2 to 5 days later as the clot retracts. It is most common in patients with elevated intraocular pressures (IOPs), hyphema greater than 30% of the anterior chamber, and with delayed presentation. Rebleeding may lead to glaucoma and synechia formation.

61.8. A 48-year-old woman presents with right eye pain, photophobia, and decreased vision after a motor vehicle collision (MVC). Physical examination reveals an irregularly shaped pupil and a small hyphema. Photophobia, decreased acuity, minimal pupil reactivity, and bloody chemosis are seen on examination. What is the most likely diagnosis?
A. Acute angle–closure glaucoma
B. Blunt ciliary injury
C. Iridodialysis
D. Scleral rupture
E. Traumatic miosis

Answer: D. Scleral rupture occurs either at the insertion of the extraocular muscles or at the limbus, where the sclera is the thinnest. A “teardrop” pupil is often seen and may be accompanied by bloody chemosis or severe subconjunctival hemorrhage. Brownish black pigment prolapse may also be seen. Intraocular pressure (IOP) may be low, but tonometry is generally contraindicated in cases of suspected globe injury.

61.9. A 26-year-old man presents with a 3-day history of right eye pain, decreased vision, and photophobia. He reports a history of left eye trauma 6 weeks prior, with hyphema, traumatic iritis, and persistent decreased vision. He is otherwise healthy. Physical examination reveals photophobia in the right eye with bilateral decreased vision. Before the past 3 days, the vision in the right eye had been perfect. What is the most likely explanation for his right eye symptom?
A. Collagen vascular disease
B. Post-traumatic conjunctivitis
C. Post-traumatic retinal tear
D. Spontaneous vitreous hemorrhage
E. Sympathetic ophthalmia

Answer: E. Sympathetic ophthalmia is an autoimmune inflammatory response in the unaffected eye, days to months after uveal trauma in the opposite eye. Pain, photophobia, and decreased vision are common. This patient had no findings consistent with conjunctivitis or collagen vascular disease, and a retinal tear would not typically be painful.

61.10. Oral antibiotics are indicated for which of the following?
A. Blepharitis
B. Chalazion
C. Dacryocystitis
D. Endophthalmitis
E. Hordeolum

Answer: C. Dacryocystitis is an infection of the lacrimal sac from nasociliary duct obstruction. Warm compresses are also recommended and may be helpful, although evidence is lacking. Warm compresses and topical antibiotics are appropriate for the other conditions. Intravitreal antibiotics are indicated for endophthalmitis.

61.11. Emergency department (ED) bedside ocular ultrasonography can provide useful information for which of the following conditions?
A. Lens dislocation
B. Retinal detachment
C. Vitreous hemorrhage
D. All of the above

Answer: D. A displaced lens can be seen in the relatively hypoechoic vitreous. Vitreous hemorrhage and retinal detachment can both be diagnosed with ED bedside ultrasonography.
CHAPTER 62
Otolaryngology*

James A. Pfaff | Gregory P. Moore

OTITIS MEDIA

Principles

Otitis media is broadly defined as inflammation of the inner ear and is a continuum of disease. Acute otitis media is defined as the signs and symptoms of an acute infection, with evidence of effusion; this has also been called acute suppurative or purulent otitis media. Otitis media with effusion (OME) includes effusion without signs or symptoms of an acute infection; additional descriptive terms include serous, mucoid, nonsuppurative, and secretory otitis media. Chronic otitis media or chronic suppurative otitis media refers to chronic discharge from the ear through perforation of an intact membrane. Recurrent otitis media is defined by three or more episodes over 6 months or four episodes in 1 year.

Acute otitis media (AOM) is one of the most common diseases affecting preschool children in the United States and represents the most common indication for antibiotic usage and pediatric outpatient visits. More than 80% of children will have at least one episode of AOM during their lifetime and, by 3 years of age, up to 40% will have had at least three episodes. In 2011, there were 6.21 million patient visits with a diagnosis of otitis media. The financial repercussions are enormous, with one estimate that it adds $2.88 billion to annual health care expenses.

Male gender, daycare attendance, parental smoking, pacifier use, family history of middle ear disease, premature birth, and lower socioeconomic status have been implicated as risk factors. Children with anatomic abnormalities, such as cleft palate and Down syndrome, have a higher rate of OM, probably because of eustachian tube abnormalities. Some immunocompromised patients, including patients with human immunodeficiency virus (HIV) infection, may have recurrent OM as an initial symptom of their underlying disease. OM and upper respiratory infections occur primarily in the winter. Breast-feeding seems to be protective. Immunizations for pneumococcus and influenza provide some protection but the decrease in overall episodes of otitis media is multifactorial. These factors include improved diagnosis, public education campaigns, and decreasing exposure to second-hand smoke. AOM is much less common in adults and is treated with the same antibiotics as for younger populations. OME is also less common in adults and is frequently associated with sinus disease, smoking-induced nasopharyngeal lymphoid hyperplasia, adult-onset adenoidal hypertrophy, and head and neck tumors such as nasopharyngeal carcinomas.

Anatomy and Pathophysiology

Eustachian tube dysfunction is the central theme of most theories of AOM pathogenesis. The eustachian tube, between the middle ear cavity and nasopharynx, ventilates the middle ear to equilibrate pressure, allows for middle ear drainage, and provides protection from nasopharyngeal secretions. In young children, the eustachian tube is short and horizontal. As individuals age, the eustachian tube widens, doubles in length, becomes more vertically oriented, and stiffens, which may explain the decreased incidence of AOM in adults. Normally, the tube is collapsed, but it opens during yawning, chewing, and swallowing.

The eustachian tube may become mechanically or functionally obstructed, decreasing middle ear ventilation. Examples of mechanical obstruction include inflammation from an upper respiratory infection, hypertrophied adenoids, and a cleft palate. Functional obstruction from persistent tubal collapse occurs primarily in young children, who have less fibrocartilage support of the medial eustachian tube than older children or adults. There is general consensus that AOM occurs as a consequence of an upper respiratory infection resulting in eustachian tube dysfunction and subsequent negative middle ear cavity pressure, causing a transudate of fluid that combines with the reflux of nasopharyngeal secretions and bacteria. As such, there is a proliferation of bacteria and viruses.

The advent of reverse transcriptase polymerase chain reaction technology and other techniques for viral identification has led to improvements in diagnosis, and thus the number of viral agents identified in the middle ear has increased. In pediatric patients, middle ear cultures have been positive for viruses 48% to 70% of the time, with viral and bacterial coinfection occurring between 45% and 66% of the time. Respiratory syncytial virus is the most common virus, but parainfluenza virus, influenza virus, rhinovirus, and adenovirus have also been found in the middle ear aspirates of children. Viruses contribute to a poor treatment outcome by increasing middle ear inflammation, decreasing neutrophil function, and decreasing antibiotic penetration into the middle ear. The most common causes of bacterial infection in children are Streptococcus pneumoniae, Haemophilus influenzae (primarily nontypeable), and Moraxella (Branhamella) catarrhalis. Streptococcus pneumoniae, Staphylococcus aureus, and gram-negative bacteria are much less common. The widespread use of the pneumococcal seven-valent conjugate vaccine (PCV-7) and subsequent pneumococcal 13-valent conjugate vaccine (PCV-13) have changed the frequency of these common organisms, with H. influenzae increasing in frequency, particularly in persistent AOM and treatment failures.

In young children, it was previously believed that gram-negative organisms and S. aureus were the causative organisms. Although these bacteria may be the causes in intubated patients or patients in the neonatal intensive care unit, healthy newborns tend to be infected by the same pathogens as healthy older children. Bullous myringitis produces bullae on the tympanic membrane (TM) in up to 5% of cases of OM in children younger than 2 years. Although it was previously thought to be caused by Mycoplasma pneumoniae, M. pneumoniae is uncommon; a culture of middle ear aspirates in this condition generally grow the usual organisms that cause AOM in all age groups. Bullous myringitis is therefore treated with the same antibiotics.

More than 70% of children with purulent conjunctivitis may have OM, a symptom complex described as the otitis-conjunctivitis syndrome, which is predominantly caused by H. influenza. Other

*The opinions or assertions contained herein are the private views of the authors and are not to be construed as official or as reflecting the views of the Department of the Army or the Department of Defense.
less likely organisms that can cause AOM include *Mycobacterium tuberculosis* (primarily in children) and *Chlamydia trachomatis* (most commonly seen in children <6 months).

Up to 10% of the general pediatric population may be at risk for developing four or more episodes of OM in the first year of life; these children are generally said to be otitis-prone. They may have subtle immunologic abnormalities or a greater baseline colonization of viruses and bacteria than the general population.

**Clinical Features**

Ear pain, unilateral or bilateral, is the most important symptom for making the diagnosis of AOM. Patients with AOM may present with a multitude of symptoms, such as cough, upper respiratory tract symptoms, poor appetite, diarrhea, vomiting, fever, and pulling at the ears, all of which are nonspecific. In fact, there is no constellation of symptoms or scoring systems that predict AOM, and examination of the tympanic membrane is essential to make the diagnosis.4

During the physical examination, the auricle and external canal are inspected for signs of erythema, discharge, and/or tenderness. If the canal is occluded with cerumen, curettage may clear the canal to improve visibility. In the cooperative child, the placement of 3% hydrogen peroxide or emulsifying drops, followed by gentle irrigation, may cleanse the canal if curettage is unsuccessful. The normal TM may be red, pink, yellow, or a normal pearly gray or translucent. The presence of erythema in itself does not indicate infection because crying or fever may cause hyperemia; however, a TM that is distinctly red (defined as hemorrhagic, strongly or moderately red) suggests AOM. Landmarks on the TM that should be visible include the pars flaccida, malleolus, and light reflex below the umbo. The presence of opacification, bubbles, air fluid levels, or retraction of the TM are suggestive of middle ear effusion. AOM is a visual diagnosis. A bulging tympanic membrane in a patient with signs and symptoms of acute infection is diagnostic of acute infection.5 Demonstration of tympanic membrane immobility by pneumatic otoscopy is useful in distinguishing the presence of effusion in cases in which the provider is uncertain, but this is difficult, even with experienced providers.6 A comparison examination of the other ear may help in confirming suspected infection.

In neonates, the TM is in a highly oblique position and normally appears thickened and opaque in the first few weeks of life. With tympanostomy tubes, even in the absence of infection, the TM may have decreased mobility, altered landmarks, opacity, or dullness. If the tube is patent, erythema and discharge indicate infection. If the tube is not patent, typical erythema, and tendon indicate AOM.

Before the use of antibiotics, there was a 20% incidence of complications from AOM, with mastoiditis and otic meningitis being relatively common. Complications are intratemporal or intracranial, occurring in adults and children. The development of either complication of OM occurs by one of three mechanisms: (1) direct extension of infection through bone weakened by osteomyelitis or cholesteatoma; (2) retrograde spread of infection by thrombophlebitis; or (3) extension of infection along preformed pathways, such as the round or oval windows or through dehiscences that are the result of congenital malformations. The use of antibiotics has led to a reduction of all complications to less than 1%.7

Usually, TM perforation occurs at the pars tensa and resolves spontaneously. It may persist for a longer period, resulting in a chronic perforation, chronic OM, or both. Chronic otitis media refers to inflammation of the middle ear that persists for 6 weeks or longer, accompanied by discharge through perforation of an intact membrane. Cholesteatoma is an accumulation of keratin-producing squamous epithelium in the middle ear and may result in erosion of bone within the middle ear cavity. It is seen most often in OME, in which retraction of the TM is a common problem, and its presence may alter the course of some treatment modalities.

The facial nerve courses through the middle ear, and facial paralysis is a known complication in OM. The exact mechanism is unknown, but the paralysis may be a result of infection, surrounding osteitis, facial nerve swelling, demyelination of the facial nerve from bacterial toxins, or facial nerve ischemia. Bony destruction as a result of mastoiditis can result in a defect over the semi-circular canals, resulting in a labyrinth fistula. The patient may present with vertigo and some degree of hearing loss.

Meningitis is the most common intracranial complication of AOM, resulting from hematogenous spread and direct invasion. Brain abscesses are usually caused by chronic otitis and are the second most common intracranial complication. Extradural abscesses, subdural empyema, and lateral venous sinus thrombosis have all been identified as complications of OM.

**Differential Diagnoses**

AOM is not common in children younger than 6 months as a result of the protection of maternal antibodies acquired transplacentally. Other sources of infection should be investigated in a febrile, ill-appearing infant (see Chapter 166). In addition to OM, other causes of otalgia include OME, trauma, foreign bodies, and complications of OM, such as mastoiditis and referred pain from the teeth, sinuses, throat, or temporomandibular joint.

**Diagnostic Testing**

Pneumatic otoscopy to confirm bulging and immobility of the TM is the primary diagnostic modality for AOM.

**Management**

Physicians in the Netherlands in the early 1990s had suggested that OM is a self-limited disease and recommended observation as an initial treatment option, followed by the use of antibiotics if the patient’s condition did not improve within 72 hours. The American Academy of Pediatrics (AAP) and the American Academy of Family Physicians developed guidelines in 2004 for the diagnosis and management of AOM and updated them in 2013.8 The guidelines cover diagnosis, pain management, observation, and antibiotic recommendations and apply to healthy children and not to those with anatomic conditions that put them at risk for infections. Given the multidisciplinary approach, we recommend adherence to these guidelines.

The 2013 guidelines recommend these diagnostic criteria:

1. Moderate to severe bulging of the TM or new onset of otorrhea not due to otitis externa or
2. Children who present with mild bulging of the TM and recent (<48 hours) ear pain (holding, tugging, rubbing of the ear in a nonverbal child) or intense erythema of the TM.

AOM can cause substantial pain, which should be appropriately addressed. Acetaminophen and ibuprofen are safe, over-the-counter, first-line analgesics. The use of opioid analgesia has not been well studied. Benzocaine-antipyrine, a local anesthetic, may be helpful in some patients with an intact TM. It has been shown to be more effective than placebo and is an additional option that we recommend for pain relief.

Children younger than 2 years, those with bilateral OM, or those with otorrhea gain the greatest benefit from antibiotic treatment but, because more than 80% of cases of AOM resolve spontaneously, the use of observation versus antibiotics has been advocated. This approach of watchful waiting for 48 hours has resulted in lower rates of antibiotic-resistant bacteria. The delay
does not worsen recovery but may be associated with transient worsening of a child’s condition.\(^7\) The observation option has been restricted to healthy children older than 6 months. In children between 6 months to 2 years of age, treatment recommendations are based on the certainty of the diagnosis and severity of illness. In patients with unilateral AOM without otitis media, observation is an option if the diagnosis is uncertain. In children older than 2 years, treatment is necessary only for patients with severe illness, defined as severe otalgia or temperature higher than 39°C (102°F) or patients with otitis media. Children older than 2 years can be treated or clinically observed. Table 62.1 summarizes the AAP recommendations.

Observation recommendations are also based on the reliability of the caregivers and ability for close follow-up. Providers should involve the parents in the discussion, with shared decision making. If there is concern about the ability to get follow-up, give parents a safety net prescription to be filled if the patient’s condition does not improve within 48 hours. Several studies in the emergency department (ED) have shown success with use of this approach. An analysis from the National Ambulatory Medical Care Survey has revealed that management without antibiotics has not increased since the guidelines were published, although children who did not receive antibiotics were more likely to have mild infections.\(^11\) There are no data on the use of observation in adult patients, so they should be treated with amoxicillin, 500 mg tid for 10 days.

The decision to treat is balanced against the medication’s adverse effects, which may include allergic reactions, gastric upset, accelerated bacterial resistance, and unfavorable changes in the bacterial flora. Several large systematic reviews have revealed that antibiotics are modestly more effective than no treatment, but 4% to 10% of children experience adverse effects from the treatment itself.\(^12\) Two randomized controlled trials comparing amoxicillin-clavulanate versus placebo in a total of 610 patients have reported modestly improved time to resolution of symptoms and otoscopic findings but with more side effects, with diarrhea being the most common.\(^13,14\) Although some authorities believe that these studies settled the treatment controversy, the studies were far from conclusive. Observation in children from 6 months to 2 year of age with unilateral AOM without otitis media, or children older than 2 years with a nontending ear or lacking severe symptoms, remains an acceptable and recommended treatment.

Amoxicillin’s cost, efficacy, safety profile, and palatability justify its recommendation as the first-line agent in the non-penicillin-allergic patient. It can be given at a dose of 90 mg/kg bid. This higher dose is preferred because it is effective against susceptible and intermediate resistant strains of *S. pneumoniae*, and because 15% to 20% of children have poor gastrointestinal absorption of amoxicillin.

In patients with reported allergies, a distinction should be made between types I and II hypersensitivity. There is only minimal cross-reactivity to cephalosporins for patients with penicillin allergy, and the use of a second- or third-generation cephalosporin is generally considered safe, unless the child has a previous adverse reaction to cephalosporins. In patients with type II hypersensitivity, alternate treatment options include cefdinir (14 mg/kg per day in one or two doses), cefuroxime (30 mg/kg per day in two divided doses), cefpodoxime (10 mg/kg once daily), and intramuscular ceftriaxone (50 mg/kg per day) IV or IM for 1 to 3 days. Patients with type I sensitivity are problematic in that macrolides have poor sensitivity against *S. pneumoniae* and *H. influenzae*, and clindamycin has poor sensitivity against *H. influenzae*. In patients with severe allergy, we recommend azithromycin, 10 mg/kg, as a first dose, followed by 5 mg/kg for days 2 through 5 or clindamycin, 30 to 40 mg/kg per day tid.

Children who have taken amoxicillin in the previous 30 days, those with concurrent conjunctivitis, or those for whom coverage with β-lactamase–positive *H. influenzae* and *M. catarrhalis* is desired should be initially treated with high-dose amoxicillin-clavulanic acid (90 mg/kg per day amoxicillin and 6.4 mg/kg/day clavulanate) tid.\(^13\)

Patients should be reevaluated in 3 days if there is no improvement. Treatment failure is defined by lack of clinical improvement in signs and symptoms, such as ear pain, fever, and TM findings of redness, bulging, or otitis media. The reasons for treatment failure may include the wrong initial diagnosis or antibiotic resistance.\(^12\) In these cases, treatment includes agents effective against the β-lactamase–producing organisms *H. influenzae* and *M. catarrhalis*. Recommended agents include amoxicillin-clavulanate (80–90 mg of the amoxicillin component/kg per day) and intramuscular ceftriaxone (50 mg/kg for 1–3 days). Table 62.2 summarizes the AAP guidelines for antibiotic treatment.

Patients with AOM for whom treatment with a conventional β-lactam antibiotic has failed and β-lactam–allergic patients for whom macrolide therapy has failed should be referred to a pediatric infectious disease specialist or otolaryngologist. These patients may need a myringotomy and treatment with a fluoroquinolone, which is not US Food and Drug Administration (FDA)–approved for children. Response to antibiotics is only one of a number of factors that affect clinical outcome. Other factors include eustachian tube function, coinfection with nonbacterial pathogens, and host immune response. Local practice patterns and antimicrobial sensitivities may also play a role in the type of treatment given. Treatment historically involved a 10-day course. Numerous studies have compared traditional treatment courses with shorter therapy, which is most appropriate for uncomplicated AOM. Patients younger than 2 years, those with TM perforations, or those with chronic or recurrent infections should be treated with a 10-day course. Children older than 2 years with a first-time infection and an intact TM can be treated with a 5- to 7-day course. The antibiotic treatment of AOM in adults is the same as for children. There is no indication for the use of

*Applies only to children with well-documented AOM with high certainty of diagnosis.

\(^{10}\) A toxic-appearing child, persistent otalgia >48 hr, temperature >39°C (102.2°F) in the past 48 hr, or if there is uncertain access to follow-up after the visit.

\(^{11}\) A toxic-appearing child, persistent otalgia, or whether the child’s family for those categories appropriate for additional observation, if offered; a mechanism must be in place to ensure follow-up and begin antibiotics if the child worsens or fails to improve within 48–72 hr of AOM onset.

Cefuroxime (30 mg/kg/day in two divided doses) reveals multidrug-resistant bacteria, seek and infectious disease specialist consultation.

1. Tonsillectomy may be helpful for older children who have a specific indication, such as nasal obstruction or chronic adenoiditis. Tonsillectomy is not beneficial, but adenoidectomy should be avoided in children who have had OME for more than 4 months with persistent hearing loss, those with hearing loss greater than 40 dB, children with structural damage to the TM or middle ear, and children with persistent OM who are at risk for speech, language, or hearing problems. Tonsillectomy is not beneficial, but adenoidectomy may be helpful for older children who have a specific indication, such as nasal obstruction or chronic adenoiditis.

Emergency clinicians may encounter three types of otitis media associated with a perforation of the TM:

1. Acute otitis media complicated by perforation of the tympanic membrane, presenting as otorrhea.
2. Otitis media in patients with tympanostomy tubes.
3. Chronic supplicative otitis media defined as tympanic membrane perforation with chronic inflammation of the middle ear and persistent otorrhea for 2 weeks to 3 months.

As noted earlier, tympanic membrane perforation is a known complication of AOM and, in most cases, will heal spontaneously. Patients presenting with AOM and otorrhea should be treated with oral high-dose amoxicillin, as if the TM were not ruptured. There is no advantage to adding topical therapy.

Tympanostomy tubes have also been used in recurrent AOM unresponsive to prophylactic antibiotics, for complications of AOM, and for complications of eustachian tube dysfunction, including TM retraction with hearing loss, ossicular erosions, and retraction pocket formation. Thus, tympanostomy tube insertion is one of the most common operative procedures for children in the United States, and emergency clinicians will frequently encounter patients with drainage from these tubes. In general, increased drainage from these tubes is as a result of an acute infection. The organisms involved are the same ones that cause AOM, particularly in children younger than 2 years, but *Pseudomonas aeruginosa*, *S. aureus*, and *Staphylococcus epidermidis* are also implicated. Fluoroquinolone drops are the only medications FDA-approved for use in patients with a nonintact tympanic membrane. In the acute setting, topical antibiotic administration with 5% ofloxacin drops to the affected ear bid or 4 drops of ciprofloxacin-dexamethasone bid for 7 days is an effective treatment. Systemic treatment (usually with amoxicillin-clavulanate, 45 mg/kg bid) should be reserved for patients showing signs of complicated or invasive infections or signs of systemic disease.

Chronic supplicative otitis media (CSOM) is one of the most common childhood infectious disease worldwide and is the most common cause of hearing impairment in the developing world, although it is infrequently seen in the developed world. Again, *P. aeruginosa* and *S. aureus* are the most common organisms. Because of the tympanic membrane perforation, we recommend topical treatment with quinolone antibiotics.

### Disposition

Patients should be seen in 48 to 72 hours if there is no improvement. Children who improve can be followed up in 8 to 12 weeks to ensure resolution of any residual effusion. Patients with complications need ear, nose, and throat (ENT) referral. Adults who have persistent OME warrant ENT referral to rule out nasopharyngeal carcinoma.

### OTITIS EXTERNA

**Principles**

External otitis is an inflammation of the external auditory canal. The external auditory canal is lined with squamous epithelial cells...
and cerumen glands that provide a protective lipid layer. This protective layer may be disrupted by high humidity, increased temperature, maceration of the skin after prolonged exposure to moisture, and local trauma (eg, cotton swabs or the use of hearing aids), resulting in the introduction of bacteria. Otitis externa (OE) is usually caused by *P. aeruginosa* and *S. aureus* but can also be polymicrobial. Occurring most often in the summer and in tropical climates, it is also known as swimmer’s ear or tropical ear.

### Clinical Features

The diagnosis is made clinically. The external auditory canal may be initially pruritic and may become erythematous and increasingly swollen. Symptoms include otalgia and ear fullness, as well as possible hearing loss or jaw pain. Physical findings include erythema or edema of the canal; pulling on the auricle or tragus classically reproduces the discomfort. There may be associated lymphadenitis, TM erythema, or local cellulitis. The disease may progress to a chronic form, with itching, eczema, and flaking of the epithelium, which may be from a bacterial, fungal, or dermatologic condition. In children, it is usually secondary to chronic OM.

### Differential Diagnoses

It may be difficult to distinguish OE from OM with drainage from a ruptured TM, particularly in children. The TM may be erythematous in both conditions, and the edema may preclude diagnosis. The discharge may be from OE or a perforated TM and, in equivocal cases, it is prudent to treat for both conditions.

Otomycosis or fungal infection can occur as a primary or secondary infection and accounts for 10% of cases of OE. Itching is the prominent symptom, often with minimal pain or otorrhea. Aspergillosis is the cause in most cases. Otomycosis usually appears in individuals in tropical climates, diabetics, and immunocompromised patients. Treatment involves cleansing and the use of acyclovir drops and antifungal ear drops, such as acetic acid, or a topical antifungal such as clotrimazole.

Furunculosis is a small, erythematous, and well-circumscribed infection of the cartilaginous portions of the external canal, usually caused by *S. aureus*. There is usually no drainage; treatment involves incision, drainage, and oral antibiotics effective for cellulitis based on local sensitivity. Cellulitis of the auricle and canal may cause erythema, induration, and other systemic signs. Clindamycin, 450 mg qid, will cover *S. aureus* and methicillin-resistant *Staphylococcus aureus* (MRSA). Skin conditions such as eczema, seborrhea, and contact dermatitis can all mimic otitis externa. A careful history about possible skin diseases, as well as medication and exposure history, should be elicited. Exposure to reactive metals such as nickel from devices such as hearing aids and chemicals from cosmetics and shampoos are also possible culprits.

Herpes zoster oticus, also known as the Ramsay Hunt syndrome, is a viral manifestation of disease affecting the auricle, with resulting facial paralysis that may involve multiple cranial nerves. It initially causes pain, erythema, and swelling, with vesicles developing approximately 3 to 7 days later. Treatment consists of analgesia and antivirals (acyclovir, 800 mg five times/day, famciclovir, 500 mg, or valacyclovir, 1000 mg tid), but there is little evidence supporting its efficacy.

### Diagnostic Testing

OE is a clinical diagnosis. No additional testing is indicated.

### Management

Treating OE involves cleaning the canal and treating the infection. The external canal may be cleaned with a small cotton swab or combination of gentle suctioning and irrigation, depending on the amount of obstructing exudates and whether there is an intact TM. Cleansing solutions include tap water, sterile saline, 2% acetic acid, and Buro’s solution.

Topical antibiotics are highly effective for OE treatment, with clinical cure rates of 65% to 80% within 10 days. A combination of polymyxin B, neomycin, and hydrocortisone (Cortisporin) can be given at a dose of 3 or 4 drops to the affected ear qid, although occasionally patients develop cutaneous sensitivity to the neomycin. Ofloxacin (5 drops) or ciprofloxacin with hydrocortisone (3 drops) bid may result in improved patient compliance. The addition of steroid drops may decrease inflammation and the formation of granulation tissue in the canal, but this has not been proven.
